DR. TAYLOR'S CASE OF MULTIPLE NEURITIS OF SYPHILITIC ORIGIN

Original Communications.

A CONTRIBUTION TO THE STUDY OF MULTIPLE NEURITIS OF SYPHILITIC ORIGIN.*

By R. W. TAYLOR, M. D.,
SURGEON TO CHARITY HOSPITAL, NEW YORK.

Among the many yet unwritten chapters on the ulterior effects of syphilis upon diatheses and dyscrasiæ, on its symbiosis with other morbid processes and conditions, and on the various tissues, notably cerebro-spinal, arterial, muscular, visceral, dermal, and mucous, is the one which shall establish its relation to the morbid process in the peripheral nerves, which is found early and late in its course, and even perhaps many years after it has seemingly disappeared from the economy. While our knowledge of the syphilitic affections of the brain and spinal cord is very extensive and in some instances full and systematic, that relating to the effect of the disease upon the peripheral nerves is notably fragmentary and unsatisfactory. This is especially the case as to the relation which syphilis bears as an ætiological factor in the causation of multiple neuritis, a subject which has as yet received the attention of only a few observers. The reasons why the multiple neuritis of syphilitic origin is so little known are, first, that our knowledge of the general subject is yet in its infancy; second, that cases in which syphilis is a causative factor (at least seemingly) are very rare; and, thirdly, that its connection with the nerve disorder is, for various reasons, such as the incompleteness of the history of the case, the possible late evolution of the neuritis, and the absence of concomitant or commensurative symptoms or lesions is overlooked.

Our knowledge of multiple neuritis may be said to have been formulated and systematized within the past five or six years, though, of course, the observations and studies of many physicians over a long stretch of years led up to the era of light. It is a subject of congratulation that American observers have played no small part in the study of this subject, and have aided materially in its partial crystallization. As it stands to-day, the subject of multiple neuritis is weakest in the direction of ætiology and pathological anatomy, but hopeful signs are to be seen on all sides, and, as time goes on, anomalous facts will be reconciled and lacunæ will be filled.

In this paper I wish mainly to put on record a case carefully observed for many years, in which, coincidently with the evolution of secondary syphilitic manifestations, a nervous disorder began and has since continued unchanged, attended with marked symptoms and leading to peculiar mutilations. It is, in my judgment and in that of friends well versed in neurology, a well-marked instance of multiple neuritis. Seeing that this paper is an *avant-courier* in this particular branch of the subject of multiple neuritis, I have thought it worth while also to present a *résumé* of its literature.

In the year 1879 Buzzard * published a lecture in which was detailed a case of sciatica with muscular wasting and weakness of the limbs, which that author considered to be caused by syphilis. In 1881 Ormerod † presented to the Pathological Society of London a case of painful enlargement of the median nerve of the upper extremity, which he thought was the result of hereditary syphilis. This communication was followed by a second consideration of this subject by Buzzard, ‡ who detailed the history of a case in which there was paralysis of the muscles of the face and of both the upper and lower extremities and of the trunk, with disseminated anæsthesia.

The next paper on this subject was by Ehrmann # in 1886, and it was followed by a communication by C. K. Mills ‖ before the American Neurological Association. Then, in 1888, Laschkewitch △ published a clinical lecture upon this subject, which is very unsatisfactory, for the reason that the history of syphilis in the case was not well established. In this same year Leyden ◊ published two lectures on inflammation of peripheral nerves, in which he speaks of a case in which he thought the nerve affection was caused by syphilis. Finally, in the recent excellent compendium of Bowlby ‡ we find a section upon neuritis of syphilitic origin, in which the cases of Buzzard and Ormerod are given and a personal case briefly detailed.

The foregoing are the only communications I can find after a tolerably extended search in medical literature. As a further evidence of the paucity of knowledge of the influence of syphilis in the production of neuritis, I may say that the author of the admirable Middleton Goldsmith lectures ‡ upon multiple neuritis which have done so much to enlighten the medical mind, both at home and abroad, does not recognize syphilis as a cause, nor does he quote a case in which such a relation was claimed, though he recognizes in his category of causes the direct action of such infectious diseases as diphtheria, variola, typhoid and typhus fevers, tuberculosis, and malaria.

In addition to the ætiological bearing of my case, I shall call especial attention to certain features of resem-

blance between its lesions and those of leprosy, which open up a subject now little known and understood.

The history of my case is as follows:

The patient is a female, married, a domestic, born in Norway, and forty years of age. While she can not be called stupid, she is far from being very bright and may be said to be rather weak-minded. She has been in America since her twenty-fourth year, and has no knowledge of ever having seen or having come in contact with lepers or having lived in the vicinity of such sufferers. She entered Charity Hospital in June, 1882, and has been under my observation for long and short periods until 1887, and has since been seen by me frequently from time to time until now. It was very difficult even in 1882 to get a clear chronological history of her illness, and to-day it is almost impossible. It thus happens that when at Bellevue Hospital, within two years, she stated that she was infected with syphilis fifteen years ago, and she gave other incorrect information as to the early phases of her syphilis. In early life she had measles, scarlatina, pertussis, and diphtheria, but she grew up a strong and healthy woman. When she entered Charity Hospital in 1882 she gave us the impression that she had been syphilitic then eight years, though various very cogent facts showed quite clearly that infection took place at a much later period. She maintained that her infection began during her first pregnancy, more than eight years before, but it seems very probable that after parturition she had a simple erythematous and furuncular eruption upon the legs, with an exacerbation of a mild form of rheumatism, from which she had suffered for years. Certain it is that her second child, like the first, was free from syphilis, and that she had not taken antisyphilitic remedies, which had induced a latent condition of the disease. Her third child was also free from syphilis, and she, before and just after its birth, showed no evidence of the disease. When she came to Charity Hospital she brought with her a baby girl (the first and only offspring of a second husband) which was two months old and was suffering from marked hereditary syphilis. The condition of the child clearly pointed to activity of syphilis in the mother. The latter had had no miscarriages after the birth of her second and third healthy children and before the birth of the fourth and syphilitic child. These facts, therefore, go to show that syphilitic infection took place in the mother between the dates of birth of her third and fourth children. Syphilis was probably contracted from the second husband, who went to sea during the woman's fourth pregnancy and has never been heard from since.

A careful consideration of all facts convinces me that the woman was infected rather less than two years prior to her first entry into Charity Hospital in 1882, therefore that she has now been syphilitic about ten years. I am thus careful in stating the case because the woman has told so many different stories, and it is important, in the study of her syphilitic history, to be correct as to its chronology.

In June, 1882, she had a typical syphilitic iritis and the copper-colored stains of a vanished eruption over the body, and particularly over the legs. She also suffered from rheumatism, which was worse at night. The truth was that the woman gave ample evidence of being in the power of active syphilis which, owing to absence of treatment, had run on unchecked. She was thin and weak, and responded badly to medicine.

Early in the year 1882 (in the last half of the second year of syphilis) she noticed that the sensation on the backs of both hands was impaired, and when she had been in the hospital a few weeks we found marked analgesia and anæsthesia over the backs of the fingers, hands, and wrists, particularly upon the left side. At this time she had pain in the eyes and dimness of vision, and the ophthalmoscope showed double neuro-retinitis. Under "mixed treatment" and local mercurial inunctions the morbid process in the eyes was promptly arrested and cured. But little effect was produced upon the causes underlying the analgesia, which extended slowly up the arms. During this time she also suffered from headaches, which were sometimes relieved by the iodide of potassium, at others by nervine stimulants (valerian, ammonia, etc.). It was noted that toward Christmas, 1882, the analgesia had extended up the arms as far as the elbows, and that it was complete on the extensor surfaces and was encroaching on the flexor surfaces.

In reviewing the case up to January, 1883, it was evident that the treatment (which, by the way, it was necessary to discontinue from time to time) had improved the patient's nutrition, had cured her iritis and neuro-retinitis, had at times relieved her rheumatism and headaches, but had had little, if indeed any, effect upon the sensory disturbances going on in the upper extremities.

It should be stated that coincidently with the analgesic symptoms pains, dull and aching and severe and lancinating, were complained of in the arms, together with a feeling of numbness and heaviness.

In February, 1883, a new order of phenomena was noted. The patient began to complain of tenderness, pain, and swelling in the left heel, and soon after in the corresponding foot. This pain extended up to the knee and was dull and seemingly deep-seated in character. It sometimes coexisted with the similar pains in the arms, and at others those of one region ceased, and again they seemed at times to oscillate between the upper and lower extremities. At this time diffuse hyperplasia was noted on the prominences of both cheeks, and a similar condition was found on the region of the left ankle. The appearances were those of acute diffuse gummatous infiltration into the skin, as well as into the subcutaneous tissue. At this time also there were tender spots of periostitis over the cranium and the headache was sometimes severe. In May, 1883, she weaned her baby, which under treatment had become healthy and blooming. At the end of 1883, a little less than two years from the date of onset of the sensory disturbances, it was found that the analgesia and anæsthesia had extended up each arm to the shoulder, being complete on the extensor surfaces and partial on the flexor surfaces. At this time also an analgesic spot was found on the dorsal aspect of the left shoulder. During all this period of increasing nervous disturbance the patient had complained of little, if any, impairment of muscular power. She took care of her baby and at times assisted in the general care of the ward, but toward the end of 1883 she burned, scratched, scalded, and in many ways injured and bruised her fingers, owing to the loss of sensation and tactile sense. At this time also she began to complain of numbness in the feet, and particularly in the toes.

In January, 1884, the following condition was noted: Beginning at the toes, the analgesia extended up both legs, but more markedly on the outer and anterior aspects, nearly to Ponpart's ligament. Though analgesic, there were spots and patches in which some sensibility to light and hard pressure could be felt. During this year the patient complained at intervals of numbness of the upper and lower extremities, and often said that her arms felt as heavy and unwieldy as if they were dead. Though the analgesia was complete from the shoulder down, the prick of a pin could be felt in the palm of the hand. It was noted at this time that examinations were made of the nerves forming the brachial plexus, and that it could not be determined that they were perceptibly thickened. For months the patient suffered paroxysmally with severe headaches, which prevented sleep at night. In the summer of 1884

the degenerative changes began in the fingers, owing to bruises, burns, and to the development of panaritium, and they continued to attack one finger after another during the following four years. These degenerative changes began in indolent ulcers and bullæ, resulting from various traumatisms which showed no tendency to heal, but caused the tissues—dermal, fibrous, and bony—to slowly melt away by molecular necrosis. In this way first the skin and fibrous tissues disappeared, and then portions of the bone in spicula and in the form of detritus. When the degeneration was not very active and extensive, healing occurred—as, for instance, when the tip of a thumb was attacked—but in most instances unsightly and painful deformities were produced, which required surgical intervention to bring about sightly and tolerably serviceable stumps. It was frequently remarked that fingers and toes which had been the seat of obstinate ulcers usually healed kindly after amputation, partial or complete, followed by proper dressing.

An inspection of the engravings will show the appearances of the hands and feet as they exist to-day. On the right hand (see Fig. 1) the soft parts of the last phalanx have disappeared; of the index finger nearly all of the first phalanx is absent, and a characteristic ulcer may be seen over its dorsum. The last phalanx and a part of the second of the middle finger, the last phalanx of the ring finger, and half of the little finger are shown to be absent. On the left hand there is loss of the distal part of the thumb; on the index finger the nail and its bed, destroyed by panaritium, may be seen; the middle finger has disappeared, owing to successive amputations; and the two remaining fingers are in fair condition.

The appearances of the feet are well shown in Fig. 2, and do not need further specification. The deformity was great and unsightly, and it grew more marked as years went on by the gradual contraction of the flexor muscles, giving the hands the appearance of claws. A person unfamiliar with the case might readily take it to be one of anæsthetic leprosy, and, indeed, several very competent men leaned toward this opinion.

During the years 1884 to 1886 the patient was in and out of the hospital at irregular periods, and the treatment was far from being as systematic and thorough as it should have been. She at one time suffered from left bursitis, at another she was attacked with gummatous infiltration in both legs, and later an iritis appeared again in the left eye, which had been attacked some years before. Then keratitis attacked this eye, and in its train left a leucoma. During this period also the patient suffered from several mild attacks of facial erysipelas, and as a consequence the atrophy of the skin of the face, which had taken place some years before, became more pronounced, and as a result a double ectropion was produced, so that the patient can not close her eyes without the aid of her fingers.

It may be well to mention the fact that the aching pains and numbness in the limbs, which began as early as 1882, were complained of during the years above mentioned.

The foregoing facts will, I think, give a very clear idea of the course of the disease in this patient and of the ravages produced by it. From 1877 until now (June, 1890) the woman's condition was not materially altered. By reason of the mutilations of the hands she has been unable to gain her living, and is capable of very little and rather limited manual labor. She can walk fairly well. In this condition she oscillates from one charitable institution to another; within a year or two she has been in Bellevue Hospital, under the care of my friend Dr. C. L. Dana, who has kindly given me the notes of her case taken by him. She is to-day fairly well nourished, has a good appetite and average strength; her mental state is fully as good if not even better than it was when I saw her first in 1882. There is diminished sensation of the cornea, but the patient can feel an object placed against it. She is in no manner hysterical. She can not move the muscles of the face to any extent so as to frown or wrinkle the forehead, which she could do fairly well several years ago. Sensation is diminished in a marked manner over the distribution of the supra-orbital frontal and nasal nerves, though there is still some sensation over the bridge of the nose. The sensation over the distribution of the occipital nerve is still good, though over the rest of the face sensation is altogether absent, except over the distribution of the mental nerve, where it is still good. There is good power in both arms and legs and no diminution of muscular sense nor ataxia. There is now some tactile sensation in these parts, though markedly diminished. Sensation on the trunk is present, though much blunted; there is a total loss of sensation from the shoulders down, except a small fold at the elbow and a narrow strip on the inside of the arms below the axillæ. On the lower limbs there is a total loss of sensation as far as Poupart's ligament anteriorly, and up to the fold of the buttock posteriorly. Plantar reflex is absent, though the patellar reflex is present. There is no ankle clonus, though there is some at the patellæ. The sense of taste is unimpaired and the vision is not perfect.

During all these years headache has been a rather constant symptom, and it has usually been benefited by large doses of iodide of potassium and of the mixed treatment. At times the patient has suffered from intermittent fever of the tertian and quartan types.

The clinical history of this case is so clear and full that I think it needs no further elaboration. Its symptoms and course point unmistakably to degenerative changes in the nerves of the face and upper and lower extremities. Throughout its whole course the case presented no symptoms pointing to lesions of the brain and spinal cord, therefore I think there can be no doubt that it is an excellent instance of multiple neuritis.* This brings us to the ques-

* Cases of neuritis affecting the upper and lower extremities and leading to deformities similar to those of my case have been published by several observers; but in these there was no history of syphilis, nor did any of their symptoms point to the origin of the affection in leprosy. Hückel publishes two such cases (Zwei Fälle von schweren symmetrischen Panaritien auf trophoneurotischer Grundlage, *Münchener medicin. Wochenschrift*, July 2 and 9, 1889)—one of a woman thirty-eight years old, and a second of a man aged thirty-seven years. In both cases there were anæsthesia and analgesia with chronic symmetrical ulcerative and necrotic processes and atrophy and paresis of muscles. The upper extremities in both cases were involved before the lower ones were attacked. Some of the cases reported by Morvan and others are similar in their clinical history and in the deformities thus produced. The reader is referred to the following articles upon this subject: Le panaris nerveux, *La France médicale*, 1881, ii, pp. 325–331, by Quinquaud; De la parésie analgésique à panaris des extrémités supérieures ou paréso-analgésie des extrémités supérieures, *Gazette hebdomadaire de méd.*, Paris, 1883, 2. S., xx, pp. 580, 590, and 624, by Morvan; Nouveaux cas de paréso-analgésie des extrémités supérieures, *Gazette hebdomadaire de méd.*, Paris, 1886, 2. S., xxiii, pp. 521, 537, and 555, also by Morvan. (The disease described in these two

tion of ætiology. As the literature and our knowledge of syphilitic multiple neuritis were almost wholly wanting during the early years of this case, I was for a time uncertain as to its real nature. But, as contributions have appeared and our knowledge of the general subject has expanded, my conviction has grown strong that the chronic morbid changes in the nerves of this patient were caused by syphilis. A brief review of the case shows that about eighteen months after syphilitic infection analgesia appeared in the backs of the hands of this woman. This symptom in her was, as I myself observed, precisely similar to what we occasionally see in recently syphilitic women, particularly those suffering from a chlorotic condition or from a neurotic or hysterical state. In most women this analgesia of the secondary stage of syphilis is transitory in character and disappears in one or more months, and in exceptional cases is found to relapse. In the present case the disturbances in the portions of the nerves situated in the dorsum of the hands did not end there, but increased until the fingers were involved, and they also slowly spread up the arms even as far as the trunk. Later on a similar disturbance appeared and ran a similar course in the legs. Coincidently with the development and course of this nervous affection we find that the woman presents at all stages unmistakable lesions of syphilis in other parts of the body, such as the eyes, the subcutaneous connective tissues, and the fibrous tissues. Certainly no history of concomitant symptoms in a case could be clearer and more satisfactory. The next question which arises is, What was the nature of the lesion of the nerves? From a study of this case, aided by our knowledge of the tendency of syphilis to produce inflammation in connective tissues, I am led to believe that the morbid change begins as a low grade of inflammatory process in the fibrous elements and envelopes of the nerves, and that, as this increases, hyperplasia of these elements occurs, which results in compression and degeneration of the nerve tissues. This conclusion is warranted by the knowledge we possess of the pathological anatomy of multiple neuritis. It is very probable that the neuralgias of syphilis are due to hyperæmia and inflammatory changes in the nerves, and that these conditions, demanding prompt relief, by reason of their severity, are usually dissipated by active mercurialization before structural degeneration of the nerve tissues has taken place. In this connection, I think, a brief history of the following case will be of interest:

A merchant, aged thirty-six, large and robust, but a little flabby, a good liver, and a fair drinker, presented an infecting chancre of sixteen days' incubation early in September, 1889. Late in October secondary manifestations—roseola, malaise, pain in joints, and erythema of the pharynx—appeared. He was at once placed upon an active syphilitic treatment, which he followed with considerable regularity for three months. At the end of this time he became negligent and indulged too much at the table, partook of too much wine, and took very little exercise. Toward the end of March, 1890, he caught a severe cold from exposure, and began to feel a slight tenderness on sitting and in walking in the left large sciatic nerve. Regarding it as an ephemeral trouble, he kept at business until the pain, which was continuous day and night, became so severe that he was forced to take to his bed. Under the influence of local mercurial frictions, with continuous dry heat, together with full doses of iodide of potassium internally, respectively thirty and fifteen grains, the severity of the pain was checked and he was able to go about with a stick in less than a fortnight. While confined to bed he had experienced pain in the parts supplied by the anterior cutaneous nerve of the same side. At this time he called attention to a number of ill-defined red patches on the inner surface of the same leg and upon the calf. Upon examination, I found six subcutaneous, not well circumscribed, doughy masses of infiltration, which were decidedly tender on pressure and the seat of soreness in walking. Urgency of business caused this gentleman to go about sooner than was prudent, and he became somewhat worse. His sciatica remained in a subdued condition, being merely a tenderness, but the pains in the anterior cutaneous nerves became rather worse. Then the subcutaneous nodules became darker in color, quite clearly circumscribed, and the seat of pain and tenderness; in other words, they developed into an eruption of typical precocious gummata. The iodide was given internally in fair quantity, and equal parts of mercurial and belladonna ointments were applied to the gummata by means of a bandage and a closely-fitting stocking. The result was that the pain in both nerves and gummata grew slowly but surely less, and that the gummata became less painful and were slowly absorbed. No local treatment was used for the neuralgia of the cutaneous nerves, but it subsided coincidently with the absorption of the subcutaneous nodules, some of which seemed fully two inches in thickness.

It is interesting to note that, synchronously with the appearance of the neuritic phenomena, typical dry onychia and separation of the nails began on several fingers of both hands and on several toes of both feet. These likewise showed signs of improvement under the local use of mercurial ointment and the general treatment. I may here remark that it has often struck me very forcibly that some of the earlier nail lesions of syphilis seem to be the result of tropho-neurosis, while others are due to inflammatory and infiltrative processes.

In this case we find that, shortly after the onset of neuralgia of the sciatic nerve in a patient suffering from early and active syphilis, true subcutaneous gummatous nodules, which we know have their nidus in the connective-tissue structures, are developed, and that the nerve changes and subdermal changes are coincidently relieved and cured by active antisyphilitic medication, local and general. I think, therefore, taking all the facts into consideration, that the conclusion is warranted that syphilis caused the nerve affection and the subcutaneous new growths by reason of its known tendency to produce hyperæmia and hyperplasia of the connective tissues. In this connection I may say that I have recently had under observation a syphilitic lady who suffered from neuralgia of the anterior crural nerves and precocious gummata of the legs, both of which disappeared under antisyphilitic treatment.

Why syphilis causes neuralgias in some cases and analgesia and anæsthesia in others is a problem yet to be solved. With only nine cases at our disposal it is evident

articles has been called Morvan's disease.) Sur un cas de panaris analgésique, *Annales de dermat. et syphiligraphie*, 1885, p. 282, by Broca; and Nouveau cas de panaris analgésique, *Gazette hebdomadaire de méd.*, 1887, p. 345, by Colleville.

that the chapter on the symptomatology of multiple neuritis of syphilitic origin can not now be written. It is worth while, therefore, I think, to present a brief and clear synopsis of the cases of other observers, since it will be of interest in connection with my own case and of aid to others in the study of this affection.*

Ehrmann's case, observed in Neumann's clinic, is reported in order to show conclusively that, in the active and earlier stages of syphilis, the peripheral nerves may be affected by neuritis. Its history is as follows:

A man, thirty-eight years old, entered the hospital on the 16th of December, presenting a hard chancre and generalized secondary eruptions. In his urine a large quantity of albumin, cylindrical epithelium, red and white blood-corpuscles, and epithelium from the pelvis of the kidney, were found. Under the influence of hot baths and iodide of potassium internally he seemed better in about six weeks, and the albumin was no longer found in the urine. A little later on he became jaundiced, and on the 29th of April periostitis of the left tibia caused the resumption of the iodide. Then, in a short time, periostitis of the external malleolus of the left side, pain in the tendo Achillis and in the gastrocnemii muscles, and swelling and pain in both cuboid bones, were complained of. Then it is noted that pains were felt in the first and second phalanges of the left ring finger, and a sensation of tingling on the ulnar side of the left forearm and in the ring and little fingers of the same. Careful examination of the brachial plexus showed that the nerves were very sensitive to pressure in their whole length, notably the ulnar nerve. This sensibility was well marked at the internal condyle, but it was still more pronounced in the middle of the anterior surface of the forearm; was very active at the ulnar side of the palm, from whence it extended to the ring and little fingers. Pressure upon the median nerve caused much less pain, but none in the radial. Examination showed that the nerves on the left side were much more distinctly felt than those of the right and unaffected side. The interosseous spaces of the left hand, between the metacarpals of the ring and little fingers, were visibly depressed, and all the muscles supplied by the ulnar nerve were atrophied. Extension of the ring and little fingers was incomplete at the phalangeal articulations, and they could not be moved the one on top of the other, nor could the patient place the ring finger over the middle finger.

Tests of sensibility showed hyperæsthesia of all the ulnar side of the forearm, especially at its lower portion. On the bend the hyperæsthetic zone included the parts supplied by the ulnar and median nerve, and slight punctures with a needle produced small bullæ, surrounded with a red areola. Ehrmann looks upon this fact as evidence of vaso-motor disturbance. Heat and cold produced pain in the hyperæsthetic zone. The electrical irritability of the ulnar and median nerves was diminished; patellar reflex was well marked on both sides, and the tendon reflex of the upper extremities was the same on both sides. A fair amount of improvement was produced by the iodide, in doses of thirty grains daily, but the symptoms were still manifest in July.

* In this connection it is well to remember that cases of syphilis in which one or more fingers of both hands have become cold and livid, and even ulcerated, have been reported by Hutchinson (*Med. Times and Gazette*, 1884, i, p. 347), by Klotz (*American Journal of the Medical Sciences*, Aug., 1889), by Baron d'Ornellas (*Annales de dermatologie et de syphiligraphie*, June, 1888, p. 35 *et seq.*), and by J. E. Morgan (*Lancet*, July 6, 1889). In the present state of our knowledge an obliterating arteritis is the ascribed cause of this condition. The relation of the nervous system to it is yet to be determined.

Buzzard's first case was that of a man, aged thirty-one, who suffered from pain in the right leg along the course of the sciatic nerve and its branches. The patient had lost flesh and the leg was weak and withered. The history of syphilis was not at all clear, and the diagnosis of a specific origin of the trouble was based largely upon a putative node on the right femur. Under the influence of iodide of potassium the pain ceased and the node was absorbed.

Buzzard's case, in his second contribution, was as follows: W. H., a workingman, aged forty-four, of previous good health, in January, 1873, had double facial paralysis, total absence of power of voluntary contraction in the muscles of either leg, the grasp of both hands was entirely lost, and there was partial paralysis of respiration and deglutition. There was incomplete paralysis of the right external rectus muscle and of the soft palate, especially on the left side. There was but little movement of the diaphragm and very imperfect action of the intercostal muscles. There was more or less anæsthesia of the body, extremities, and face. A sense of numbness and weight was complained of in each leg; the brain and viscera were seemingly in normal condition. This condition began a month previous, with numbness in the finger-ends and weakness in the legs, together with a pin-and-needle sensation and numbness in the calves, thighs, and buttocks. In a few days he could use neither arms nor legs. Owing to the syphilitic history obtained, he was treated with the iodide of potassium, and later with mercury. Improvement soon began, and in six months the patient was able to resume his employment, and later on was pronounced to be entirely recovered.

Ormerod's case was that of a woman, aged twenty-three, who presented an enlargement of the left median nerve in the upper arm. The nerve was thicker than a quill, and the muscles supplied by it were wasted. The two last joints of the index and middle fingers and the last joint of the thumb were anæsthetic. The skin of the last joint of the index finger had been red, glossy, and ulcerated, but the condition had passed away under treatment. There had been an attack of pain in the nerve five years ago, but this had passed off, leaving no permanent damage. Two and a half years ago the pain had recurred, leaving the present condition. The patient presented several unequivocal signs of congenital syphilis. In favor of this view were the facts that no other cause could be assigned, that the ulcer had healed under iodide of potassium, and that deafness had much increased during the few months preceding the last attack of neuritis.

In the discussion of this case Mr. Jonathan Hutchinson stated his belief that the patient's condition was probably dependent upon syphilis, but he had never seen a similar case in congenital syphilis, although he had seen an example of neuritis of one of the nerves of the arm from the acquired disease.

Dr. Mills regarded cases of pure and simple multiple neuritis as rare. He reported three with a distinct syphilitic history. He frequently found certain cases of paralysis in which a clear history of syphilis or of chronic alcoholism, or both, was present. These two factors were so often conjoined in the history of the same case that it was sometimes difficult to separate such cases into two subdivisions, one of which represented a type clearly syphilitic and the other clearly alcoholic. Sometimes he had been able to do this. His three cases, of which he presented the notes (which, unfortunately, are not published), presented the usual features, sensory and paralytic, of multiple neuritis, and he re-

marks that this affection, when due to alcohol, is almost similar in its symptomatology. Specific treatment benefited the former but had no effect upon the latter. Mills states that in these cases there are points of resemblance between neuritis, myelitis, and poliomyelitis. He believes that there are no clear diagnostic points between these affections which would enable us to say positively that here was a case of multiple neuritis, there one of diffuse myelitis, and, still further, one of myelitis anterior. There were symptoms which rendered the diagnosis probable, but more could not be said in certain cases with safety.

Leyden's case is reported in a very cursory manner. It is as follows: A healthy young man, accustomed to muscular exercise, was attacked by terrible pains and paretic weakness of the arms, with distinct atrophy and pathological conditions with the electric current. When he consulted Leyden he presented a florid secondary eruption, therefore his neuritic symptoms were ascribed to syphilis. Later on the patient had a specific affection of the liver, and was finally cured of his syphilis, as well as of the neuritis.

Bowlby * speaks of the case of a man, aged fifty-four, who had suffered from syphilis for many years, in whom a gradual paralysis of the parts supplied by the ulnar nerve had commenced ten years before he came under observation. The hand was clawed, the interossei muscles and those forming the ball of the little finger were extremely wasted, and there was very definite atrophy of the ulnar side of the forearm. The skin supplied by the ulnar nerve was quite anæsthetic. This nerve could be felt behind the elbow as a thick, hard cord, not less than four or five times its natural size, the thickening extending along the trunk for about two inches. It was slightly painful and tender.

Several gentlemen of prominence who have seen my case were disposed to consider it to be one of leprosy. In the light of the history given, I think such a diagnosis is untenable. In this connection, however, I have thought it worth while to summarize the following case, in which a coincidence of leprosy and syphilis in the same subject is claimed. With this view I am not at all in accord, and I think that the facts which I have brought forward in this essay will convince others, as they have convinced me, that in Kaposi's case the nervous symptoms were produced by syphilis alone.

Kaposi's case,† shown before the Imperial Society of Vienna in 1888, was that of a man, aged thirty-one years, born of healthy parents in a country where lepra is not epidemic. In 1884 he contracted syphilis. After several years passed in Asia he returned to Germany for treatment of his syphilis. At that time he presented new lesions—ulceration of the palmar surface of the right index fingers, pains radiating from that finger to the shoulder, red spots upon the right hand, anæsthesia of the index finger, and hyperæsthesia of the other fingers of this hand. Later on new patches, similar to gummata, appeared. The circumference of the right arm became less than that of the left, while at the right wrist the circumference was a little greater than that of the left. The right index finger was longer than that of the left, and it presented a fusiform thickening. The right hand was covered with irregularly distributed, diffuse patches. The movements of the right arm were impaired, though muscular contractions were normal.

There was infiltration in the right superciliary region from the middle of the brow to the external angle of the eye, which at its internal edge was hard and elastic and became soft as it progressed outward. This infiltration, like that of the hand, was painful on pressure but in parts anæsthetic. Around it was a zone of hyperæsthesia. There were anæsthetic patches also on the hand.

Kaposi, in considering the ætiology of this case, says that the view that it might be due to syphilitic neuritis could surely be excluded for the reason that a spinal nerve can not be affected by syphilis unless it is in contact with a gumma. Further, he thinks that if syphilitic neuritis did exist it was not because of the cutaneous lesions, for he does not think that they were of syphilitic origin. Lupus was also excluded by him.

The clinical tableau, consisting of the anæsthesia, the rapid succession of the eruptions, the nature of the infiltration, the neurotic symptoms, and the functional troubles, he thinks prove conclusively that it was due to anæsthetic leprosy.

Kaposi states, however, that neither he nor his assistants could find the bacillus of leprosy, but he explains this by the fact that the disease was as yet in its initial stage. Further, he states that Hansen says that bacilli are never found in anæsthetic leprosy.

Kaposi looks upon this case as one showing the existence of syphilis and leprosy in the same individual, and states that it is the only example of this morbid coincidence which he has seen.

Danielssen once successfully inoculated a leper with syphilis.

ESSAY UPON THE CLASSIFICATION OF THE VARIOUS FORMS OF APPENDICITIS AND PERITYPHLITIC ABSCESS,

*WITH PRACTICAL CONCLUSIONS.**

By ARPAD G. GERSTER, M. D.,

SURGEON TO THE GERMAN AND MOUNT SINAI HOSPITALS; PROFESSOR OF SURGERY AT THE NEW YORK POLYCLINIC.

Up to within a recent period of time it was the prevalent belief that perityphlitic suppuration was located retroperitoneally, and most generally in the iliac fossa, whence it found its way to the surface by pushing aside the peritoneal reflection corresponding to Ponpart's ligament. Willard Parker's method of incising perityphlitic abscess was based upon this view.

It can not be denied that the development of most circumappendicular abscesses seems to confirm this view, and that the rules laid down by Parker for the treatment of this group of suppurative processes have yielded, and continue to yield, very satisfactory results in very many instances.

* Read before the New York Surgical Society, May 14, 1890.

Still, it must be said that the exceptions to Parker's type are considerable in number. Formerly they were classed as cases of general or localized "idiopathic peritonitis." Their treatment was non-surgical, and their issue very uncertain and often fatal.

We owe the better understanding of the elements of this phenomenon to Treves and Weir, but principally to McBurney, who demonstrated that in the vast majority of instances the formation of abscess in the right iliac fossa was due to intraperitoneal inflammatory processes, mostly of the vermiform appendix, and commonly accompanied by ulceration, necrosis, and perforation of this viscus. The frequency of the location of perityphlitic abscess near the parietes of the right iliac fossa is explained by the frequency of the superficial *situs* of the appendix in this region. In these cases the type of development so well described by Parker will prevail. But in a very large proportion of instances the vermiform appendix, either congenitally or in consequence of acquired peculiarity, occupies a deep situation, and in these cases an appendicular perforative process is sure to cause a deep-seated intraperitoneal abscess, more or less distant from the surface, hence infinitely more grave and dangerous both as regards its deleterious possibilities and the difficulty of diagnosis and surgical management. As soon as it became clear that widely different intraperitoneal forms of suppuration might be caused by extension from the appendix, and that their manner of development was wholly unforeseen and unaccountable, a violent oscillation in therapy was initiated by those who proposed, in all cases where the appendix was suspected of causing trouble, a bold exploration by abdominal section, and the extirpation of the appendix, or evacuation at all hazards of the purulent collection, wherever it might be found, and all this without delay.

Though this bold course of therapy has, in spite of its experimental character, yielded very good results in the hands of various surgeons, and although its adoption was absolutely necessary for establishing a clearer understanding of the nature of the morbid process in question, nevertheless it must be remembered that a vast proportion of perityphlitic abscesses do not need operative invasion of the free peritoneal cavity for their successful cure, and that a sweeping advice to the general profession to open the peritonæum in every case where appendicular trouble is suspected is, for obvious reasons, fraught with much unwarrantable danger.

Formerly it was considered purely accidental whether an intraperitoneal abscess would appear here or there, and the variability of the surroundings and location of these abscesses was deemed so irregular and erratic that, to the author's knowledge, no attempt was ever made to study the question whether a certain order of development did not prevail even in those forms of perityphlitic abscess which could not be classed with the well-known inguinal type described by Parker. If some light could be thrown upon the detailed nature of these seemingly erratic forms of circumappendicular abscess, instead of the crude general advice to "perform laparotomy," more precise, hence safer, methods of treatment would suggest themselves.

Let us first emphasize the fact that all intraperitoneal abscesses are of visceral origin, and that perityphlitic abscess in particular is due to inflammatory processes located in the vermiform appendix. Though not always, this form of abscess is mostly established within the peritoneal sac.

The proof of this assertion has been so manifold that it is only necessary to refer to the numerous cases of early appendicitis reported by McBurney and other observers, in which, on laparotomy, the free appendix was found to be tightly distended by a copious exudate, and more or less erect by dint of its extreme distention; its walls thickened, hyperæmic, occasionally exhibiting unmistakable signs of circumscribed necrosis with perforation imminent. This distension was uniformly produced by occlusion toward the gut. Occasionally decay had progressed to actual perforation and the formation of incipient abscess, surrounded by a protective barrier of recent adhesions of the vicinal serous surfaces. The appendix was invariably found to be the starting point of the trouble, and the affection, with rare exceptions, always intraperitoneal. Aside from the numerous instances in which the intraperitoneal and appendicular character of perityphlitis was established by positive observation, the following case may serve to show that the retroperitoneal space back of the iliac fossa is not the seat of abscess in typical cases of perityphlitis. In the spring of 1887 Dr. Lellmann, then on duty in the German Hospital, requested the author to operate on a case of perityphlitis pertaining to his service. The operation was delayed twenty-four hours on account of a misunderstanding, and the next day—a dense, painful tumor being found in the right iliac region—incision according to Parker was done, in spite of the circumstance that the size of the swelling had somewhat diminished since the previous day. The peritoneal lining of the iliac fossa was easily stripped up two inches beyond the external iliac vessels, so that the tumor was freely raised with it from the underlying tissues. No sign of inflammation was found, and, as the case was mending, it was not deemed prudent to incise the peritonæum. The very deep wound was drained and closed, but no pus appeared. Simultaneously with the healing of the incision the tumor disappeared, and the man was discharged cured within a fortnight after the operation.

We need not do more than hint at the causes of appendicular inflammation. Let us first mention the impaction of foreign bodies entering from the gut, acute or chronic forms of catarrhal or ulcerative (typhoid) enteritis, transmitted from the colon and leading to simple hypertrophy or to ulceration, both of these causing irregular constriction mostly in the vicinity of the attachment of the appendix. Another not infrequent cause of stenosis is the doubling upon itself and fixation of the appendix in this position. Stenosis by flexion is thus produced (F. W. Murray, *N. Y. Med. Jour.*, May 24, 1890, p. 564). With the establishment of hypertrophy and stenosis a loss of contractile power is associated, leading to more or less complete retention and to the inspissation of fæcal matter, which finally assumes the shape of one or more globular concrements. As long as the communication with the colon is fairly open, no local symptoms need prevail. As soon as the stenosis becomes considerable, the well-known signs of appendicitis make their appearance. If they are due to a passing state of catarrhal hyperæmia, their acuteness will vary in proportion with the intensity of the stenosis. Thus, with the cessation of causal intumes-

cence and the elimination of the stenosis maintained by it, all trouble may seemingly or really disappear. A case reported by Shrady * aptly illustrates this train of symptoms:

A physician had had four distinct attacks of appendicitis, in all of which the question of operation arose. Dr. Shrady had seen the patient at New York in three of the attacks, all of which were well pronounced, while the fourth occurred in Paris, where the patient was seen by a distinguished surgeon, who made a like diagnosis. There also the question of an operation came up. Each attack was attended with all the usual severe symptoms which would appear to usher in the formation of an abscess; there was dullness, tenderness, more or less rigidity, and some œdema in the neighborhood of the cæcum. In each attack the advisability of operation was freely discussed. The patient was willing to take the risks, but in each instance the symptoms gradually disappeared, and he recovered. He asked Dr. Shrady, should he survive him, to examine his appendix, which was done when death occurred, some time subsequently, of another cause. *The appendix was found perfectly sound.* There was not the slightest appearance of any inflammation around it; it was not even thickened.

Where ulcerative processes have led to the formation of a permanent cicatricial contraction, the appendical trouble is apt to persist even after the cessation of the causal disorder of the intestine. Passing states of local intumescence are then more likely to lead to complete occlusion of the communication between gut and appendix, with serious consequences. But even in these cases temporary improvements are possible with the diminution of the acute swelling of the cicatricial mass.

Before attempting a practical classification of the phases of appendicitis and of the localities in which circumappendicular suppuration is to be observed, this fact has to be pointed out: that, unfortunately, the acuteness or mildness of the local or general symptoms is not an invariable index of the ultimate gravity of a given case. Sometimes fatal cases will set in with a very deceptive mildness of appearances. On the other hand, a very alarming beginning may be followed by resolution or a tractable state of affairs. Hence it must be insisted on that, in reference to this trouble, all therapeutic advice has only a conditional value —to be weighed and accepted or rejected by the surgeon in each separate case.

A. Acute Appendicitis (without Tumor).

(*a*) *Simple Appendicitis (No Tumor).*—Anatomy teaches that in the supine body the attachment of the vermiform appendix can be found directly underneath a point located two inches from the anterior superior spine of the ilium, on a line connecting this bony prominence with the navel. Whenever acute and persistent pain appears in this region, accompanied by fever and retching, the pain being markedly increased by palpation of this area, trouble of the appendix can be confidently diagnosticated. In women, bimanual palpation ought to exclude the presence of an inflammatory process of the displaced uterine appendages. Though the local and general symptoms may be very alarming, tumor can rarely, if ever, be detected in the early stages of the affection. Meteorism is also absent.

In view of the impossibility of foretelling whether, in a given case, spontaneous evacuation of the contents of the appendix or perforation is to take place, and in the latter case whether a superficial or a deep-seated abscess is to develop; and, considering the fact that laparotomy followed by excision of the appendix has yielded uniformly good results if done before the access of perforation, it is safe to follow McBurney's advice, which recommends laparotomy and removal of the appendix whenever severe symptoms persist and increase for more than forty-eight hours.

The steps of the operation are these: A longitudinal incision, four or five inches long, parallel with and just outside of the outer margin of the right rectus muscle. Having opened the peritonæum, the appendix is found, which will be rendered easy by first ascertaining the location of the caput coli. The mesentery of the appendix is included in a double ligature of stout catgut and divided. Then the root of the appendix is secured by two ligatures, between which the viscus is cut off. The mucous lining of the stump is either seared with the thermo-cautery, or, after careful disinfection, is touched with a few drops of perchloride-of-iron solution and dried off. Then the stump is dropped back and the external wound is closed.

Case.—Miss F. L., aged twenty, has had altogether sixteen or eighteen attacks of appendicitis within two years. Characteristic local pain, irregular fever with temperatures reaching 104° F., no tumor. Uterine appendages normal.

April 20, 1890.—Laparotomy. The free appendix is found very much thickened, its distal half distended and bent upon itself, containing a quantity of fœtid serum. It was removed. Uninterrupted recovery.

(*b*) *Perforative Appendicitis (No Tumor).*—Sudden increment and extension of the local pain followed by symptoms of collapse, such as profuse cold sweating, a thready pulse, anxious expression, pallor, frequent vomiting, and the appearance of meteorism are indications that perforation and infection of the peritonæum have taken place. This rarely occurs before two or three days after the inception of the trouble. The violence of the symptoms will depend on these factors. If the extent of the perforation is small, and only a small quantity of the infectious contents of the appendix has made its way into the peritonæum, a limiting barrier of protective adhesions may be thrown about the infected area within an hour or so. In this case the alarming features of the case will somewhat subside and a tumor is apt to develop. If, on the other hand, the perforation is large or multiple, a considerable volume of infectious material will suddenly escape. Lively peristaltic action will widely distribute it, and more or less extensive local or, in the worst cases, general septic peritonitis will be established.

The absence of tumor in conjunction with very acute local and general symptoms represents an extremely grave combination of things, its meaning being a generalizing peritonitis. In these cases the prognosis is very doubtful, and it will be extremely difficult to save the patient, even

* George F. Shrady, Meeting of Practitioners' Society of N. Y. *Med. Record*, April 26, 1890, p. 479.

by the most resolute measures. If laparotomy is immediately done, the focus laid open, wiped out clean, the appendix removed, and the cavity packed and drained, some chances may still be present for the patient's recovery. But where, on account of delay, numerous and widely disseminated abscesses have established themselves in the more remote parts of the peritoneal cavity, the patient's death is nearly certain. Prolonged exposure, the impossibility of a sufficient evacuation and drainage of the foci which are found, finally the overlooking of distant foci located in the loins, in front and behind the liver, will sufficiently explain this fact.

Case I.—William Sachse, aged forty-eight, liqnor-dealer, was treated since September, 1889, in the internal department of the German Hospital for alcoholic nenritis. No habitnal constipation.

March 23, 1890.—Sndden chill. Temperatnre, 105°. Slight amygdalitis. No abdominal symptoms. The temperatnre remained high, although the patient's howels were well purged with calomel on March 25th. Had a chill in the preceding night, another one in the afternoon, complaining the first time of hellyache.

27th.—Pain well marked in ileo-cæcal region. Was transferred to snrgical service. Temperatnre, 104·4° F. Meteorism, intense pain in ileo-cæcal region, but no tumor and no dullness. Vomited only once. Laparotomy at 3 P. M. McBnrney's incision. Peritonænm filled with turbid sernm. Omentnm widely adherent to cæcum, in front of which an adherent and very mnch thickened and elongated vermiform appendix was found. On freeing this, a large, irregular abscess cavity was opened, which did not anywhere approach the parietes, and which was sitnated helow and behind the cæcum, its walls heing formed everywhere hy intestines. At the root of the appendix a large perforation was seen, with three globular fæcal concrements lying in front of and ontside of it. The appendix contained three more globular concrements of the size of a small marhle. The appendix was isolated, tied, and cnt off. Another large abscess situated in the median line, and a third one in Douglas's pouch, were opened, irrigated, and drained. Hasty partial closnre of incision after packing and drainage of the abscesses on account of collapse. In the night the temperatnre rose to 106° F., and the patient expired toward midnight. Post-mortem examination revealed three more abscesses, one sitnated high np behind the liver.

Case II.—David Danziger, tailor, aged twenty-two. General peritonitis due to perforative appendical trouble of six days' duration. Laparotomy Jannary 29, 1889, at Mt. Sinai Hospital. Seven abscesses were opened and drained. Patient seemingly improved, the quality of the pulse improving. Vomiting ceased, hnt he collapsed snddenly thirty honrs after the operation and died. Post-mortem examination revealed three perihepatic ahscesses.

B. Acute Appendicitis with Tumor; Perityphlitic Abscess.

Whenever perforation of the free appendix occurs, the invasion of the peritonæum is regularly signalized by the usual symptoms of perforative peritonitis. As before mentioned, a circumvallation by adhesions will form in those cases in which only a small quantity of infectious material has escaped. This seems to be the usual course of events. Occasionally, however, the inflamed parts of the appendix will first become adherent, and then be perforated. In these cases the alarming intermezzo possessing the typical aspect of perforative peritonitis will be missed, and the abscess will develop without a tendency to meteorism and collapse, and with a gradual but steady growth of the mainly local symptoms. The complex of symptoms has little of the character pertaining to peritonitis, and resembles that of an ordinary abscess.

By contiguous extension, which is mostly slow, these abscesses may assume very large proportions. Neglected for a long time, especially if they are limited by intestines only, their secondary rupture, followed by a chill and further extension, or even their generalization, may occur. This, however, is not common in the early stages of the process. The only case of this kind observed by the author occurred nineteen days after the inception of the trouble.

Case.—H. D., clerk, aged twenty, subject to alvine sluggishness, contracted, after a more than nsnally severe spell of constipation. a deep-seated, hard, painful, perityphlitic swelling. Cathartics failed to relieve the howels, and, high fever with vomiting having set in, the author was consnlted.

May 1, 1878.—Typical swelling of a cyliudrical shape was made ont in the right groin, and a nnmber of repeated large injections of tepid water into the gut were employed without success.

3d.—The peritoneal symptoms, notahly vomiting, became very distressing, wherefore this therapy was ahandoned and opium treatment begnn. At the same time an ice-hag was placed over the swelling. The change effected a decided improvement in the snbjective symptoms, but the swelling continned to increase and the fever remained nnrelieved.

17th.—Spontaneons evacnation of a large, formed stool occnrred.

19th.—The general condition hecoming very poor, incision was urged, bnt was firmly declined hy patient and parents. Snddenly, in the night of the same day, perforative symptoms developed. The patient died, May 20th, of septic peritonitis. Post-mortem examination demonstrated an internal perforation of the ahscess, and pntrid septic peritonitis. Had the patient consented to the operation, the case might have turned out differently. Perforation took place on the nineteenth day after the invasion.

The presence of a tumor, which always indicates the existence of protective adhesions, implies a certain amount of temporary security and, under certain circumstances, may justify a short delay of the operation.

Types of Acute Perityphlitic Abscess.

Although the classification of perityphlitic abscess according to location can not be made with geometrical precision, yet it will be found that most cases can be naturally massed in a series of roughly defined groups. The small number of intermediate or transitory forms does not vitiate the practical value of this grouping, upon the right understanding of which must be based some important variations of the operative technique.

It is the author's wish to firmly maintain the importance of the principle that every intraperitoneal abscess should, if possible, be opened and drained without invading the normal peritoneal cavity—that is, through existing planes of adhesion to the parietes. With few exceptions, all perityphlitic abscesses have such an approachable side. To study, to ascertain, and to utilize them is the duty of the

conscientious surgeon. It is idle to state that safely incising and draining an abscess through a laparotomy wound—that is, through the free peritoneal cavity—is an easy or indifferent matter. No competent person will believe it.

1. *Ilio-inguinal Type* (Willard Parker's abscess).—The normal situation of the caput coli and appendix vermiformis near the parietes of the right iliac fossa has the consequence that the great majority of circumappendicular suppurative processes will naturally establish themselves so as to have for one of their limiting walls the parietal peritonæum of that region. This has led to the erroneous belief that perityphlitic abscess is normally located behind the peritoneal lining of the iliac fossa.

This situation involves the great practical advantage that the abscess can be permitted to assume certain proportions so as to render its incision simple and free from the danger of invading the normal peritoneal cavity. Therefore, when an immovable tumor develops in the right iliac fossa soon after the inception of the malady, it is safe to wait a few days until the abscess has assumed a certain size. On the fourth, fifth, or sixth day it may be safely incised. Searching for pus with a hollow needle is superfluous when the abscess is superficial—that is, immediately beneath the parietes; dangerous if it is deep-seated, as the gut might be thus injured or the healthy peritonæum infected.

Case.—Francisca Bertrand, aged forty-five, was taken ill with fever early in July, 1882, and developed a deep-seated, painful swelling in the left iliac fossa, with high fever and peritonitic symptoms. On the afternoon of August 5th probatory puncture brought out some pus, wherefore, with the aid of the family physician, Dr. Assenheimer, incision was practiced by Hilton's method. A large quantity of pus escaped, and a drainage-tube and antiseptic dressing were applied. In the following night very acute peritonitis set in, to which the patient succumbed August 6th. No doubt the reflection of the peritonæum was injured, and part of the pus must have entered the peritoneal cavity.

The only safe way of opening these abscesses is by methodical and careful dissection, layer by layer being divided by an ample incision placed through the longer axis of the tumor. The vicinity of pus will become manifest by the discoloration and condensation of the tissues. When the abscess is opened and the bulk of its contents has escaped, a gentle exploration by the index-finger is advisable to detect recesses or a foreign body. But all rough treatment of the walls of the cavity by scraping, tearing, or rude squeezing is reprehensible, as it may lead to inward rupture. For the same reason search for and removal of the ulcerated or necrosed appendix from the abscess is to be avoided as unnecessary and dangerous. Two drainage-tubes are slipped into the cavity and fastened in the usual manner. They will facilitate irrigation without causing undue distention. A daily change of dressings will be required for the first week or ten days. As soon as the discharge becomes scanty and serous, the tube should be removed.

The ilio-inguinal type is undoubtedly and fortunately the most common form of perityphlitic abscess, and its time-honored therapy as laid down by Parker will have to be retained as safe and successful.

In sixteen cases of the ilio-inguinal group operated on by the author according to Parker's plan, only one terminated fatally, by erysipelas. The patient was under treatment for hip-joint disease when, unfortunately, the complication with perityphlitic abscess set in.

Case.—Ernestine S., servant-girl, aged nineteen, admitted March 2, 1880, to the German Hospital, with the diagnosis of hip-joint disease, the symptoms of which were indubitably present. Emaciating fever, and the characteristic flexion and adduction of the thigh, together with swelling of the gluteal and infrapubic regions, seemed to admit of no doubt. Examination under ether, however, revealed a fluctuating swelling of the right groin, which yielded pus on puncture, and was incised. A large quantity of pus and the stem of an apple or pear were evacuated. Another incision below Poupart's ligament established drainage of an abscess communicating with the perityphlitic gathering. The lower extremity was put into Buck's extension, and the cavities were daily irrigated. Operative measures, directed against the profuse discharge from the lower incision—that is, drainage or exsection of the hip joint—were contemplated, when the girl contracted erysipelas, and died of it in May, 1880. Post-mortem examination established the fact of hip-joint suppuration, a communication of the perityphlitic abscess with the joint being found, by way of the iliac bursa.

2. *Anterior Parietal Type.*—Next in frequency to the ilio-inguinal form of perityphlitic abscess is the type according to which the bulk of the purulent collection is found immediately behind the anterior abdominal parietes of the right side. Frequently this is associated with a more or less apparent ilio-inguinal tumor, and might be looked upon as its extension. The swelling is generally found behind the right rectus muscle, its shape vertically elongated, its upper limit occasionally extending beyond the level of the navel to the hypochondrium, its proximal margin to or beyond the median line. When an unmistakable continuation of the tumor can be traced into the right iliac fossa, the abscess can be safely opened above Poupart's ligament, as in the preceding group. But occasionally the upper extension will require a separate incision.

Case I.—Abraham Jacobson, tailor, aged twenty-two. Perityphlitic abscess of six days' duration, the iliac tumor extending inward and upward to the inner margin of the rectus muscle, the space above Poupart's ligament feeling empty.

November 19, 1888.—Typical incision at Mount Sinai Hospital, a little below and to the inward of the anterior superior spine; drainage. Retention of pus in the upper pocket, hence, November 26th, second direct incision. Rapid improvement.

January 17th.—Discharged cured.

Case II.—David Frank, butcher, aged forty-two. Perityphlitic abscess of eight days' duration; tumor extended upward along the line of the rectus muscle to within a hand's breadth of the costal-margin.

December 8, 1889.—Incision two inches and a half to the inward of the anterior superior spine. Evacuation of about a quart of pus; depth of abscess, twelve inches; though the wound was doing well, surgical delirium set in, and the patient was transferred to his home December 24th, where, as his family attendant reported, he soon recovered entirely.

When it is found that the iliac fossa is normal and entirely void of resistance, and a circumscribed tumor can clearly be felt some distance from the ilium and Poupart's

ligament, it is necessary to ascertain where to make a safe incision. If the extent of the tumor is great, a direct incision might be confidently made. But if the superficial extremity of the tumor is small, it will be safer to first open the peritoneal cavity in the median line by a small incision, and digitally explore the exact relations and extent of the adhesion. Having thus located the abscess, the exploratory cut is closed, and the abscess is incised by a direct route.

Case I.—Miss Evelyne H., school-teacher, aged twenty-three. Perityphlitic abscess of two weeks' duration. Small tumor to the right of median line, underneath right rectus muscle. Iliac fossa empty. *Per vaginam*, tumor was felt adherent to anterior abdominal wall, and with it bimanually movable backward and forward.

March 7, 1890.—Exploratory laparotomy in median line below the navel. Just to the right of incision, partly solid, partly fluctuating mass could be felt, its walls being evidently formed of intestine, among which the empty appendix was seen firmly attached. By passing the finger around the attachment of the tumor to the anterior abdominal wall, it was found that the iliac fossa contained healthy intestine, and that the tumor was in no wise connected with it. Fixation of tumor by fingers in abdomen; puncture through abdominal wall; fœtid pus. Closure of laparotomy wound by suture. It was sealed with a strip of rubber tissue moistened with a little chloroform. Incision of abscess along the line of puncture; evacuation of five ounces of pus. Uninterrupted recovery. Discharged cured, April 10, 1890.

Case II.—Mark Beermann, hat-maker, aged nineteen. Perityphlitic abscess of seven days' standing. Somewhat movable tumor underneath right rectus muscle on a level with umbilicus. Iliac fossa normal.

November 30, 1889.—At Mount Sinai Hospital, median exploratory laparotomy. Location of adhesion, which was very limited, was established by digital exploration. Closure of laparotomy wound. Incision and drainage of abscess. Discharged cured January 11, 1890.

Perityphlitic abscess of the anterior type may extend to and beyond the median line, when it will hold close relations with and may perforate into the bladder.

Case.—Henry Marks, aged seventeen, suffered from habitual constipation and frequent attacks of colic. In June, July, and August, 1878, severe attacks of colic were noted and overcome by the use of purgatives.

August 25th.—Dr. L. Weiss, the family attendant, made out typhlitis and ordered a laxative, which, however, failed to relieve the patient. Thereupon opium was methodically exhibited until September 6th, when the patient had a spontaneous and copious, formed evacuation.

September 7th.—The temperature rose to 104° F.; the external swelling in the right groin became very marked.

10th.—The author saw the patient in consultation with Dr. Weiss. A uniform puffy swelling was found occupying the right groin, and was extending beyond the median line of the abdomen. Frequent urination distressed the patient a good deal, who exhibited the usual hectic symptoms of long-continued suppuration. Deep fluctuation was made out, and evacuation of the abscess was determined upon. The transversalis fascia being gradually exposed, it was found infiltrated and firmly attached to the underlying tissues. A probatory puncture made in the bottom of the wound, close to the os ilium, gave pus, whereupon the abscess was freely incised, and a large quantity of matter was voided. No foreign body could be found. Digital exploration demonstrated a long sinuosity extending toward the median line to a pocket occupying the prevesical space. A drainage-tube was placed into the main abscess, another one was carried into the prevesical space, and the wound was dressed with carbolized gauze. The patient's wretched condition at once commenced to improve; appetite and sleep returned, and the profuse night-sweats disappeared.

20th.—The drainage-tubes became disarranged, and were found slipped out of the wound. Difficulty was experienced in replacing them, and symptoms of retention, with renewed pain and fever, set in again.

23d.—The author again saw the patient, and replaced the tubes. A considerable quantity of pus was found in the prevesical pocket. From this date on uninterrupted improvement was noted, and the patient got up October 10th. October 20th, the tubes were withdrawn, and October 30th the fistula was closed.

In this case imminent perforation of the bladder wall was prevented by timely incision.

3. *Posterior Parietal Type.*—Whenever perforative processes occur in an appendix located near the posterior parietes of the peritoneal cavity—for instance, near the right sacro-iliac synchondrosis or the lumbar region—the resulting abscess will naturally have a deep situation. Cases will occur in which incision of such an abscess can not be made unless it be done through a laparotomy wound. But there can be no doubt that in a certain proportion of these cases a safe incision may be made from behind.

Case I.—James Solomon, schoolboy, aged thirteen, April 18, 1889. Perityphlitis of five days' standing. In consultation with Dr. W. Morse, an indistinct, very deep-seated, and painful tumor was felt in the region of the sacro-iliac juncture of the right side. By April 22d the tumor had considerably enlarged, and seemed to lie just beneath the right rectus muscle. At Mount Sinai Hospital laparotomy was done the same day over the site of the swelling, which was found to hold no connection whatever with the anterior abdominal wall, but was firmly adherent to the posterior wall of the pelvis. The ascending colon formed the outer wall of the tumor. The appendix could nowhere be found, and was undoubtedly imbedded in the mass of the tumor. The anterior wound was closed, and a long hollow needle was thrust into the region of the tumor from behind, entering the pelvis a little to the inward of the line of the posterior superior spine, its direction being downward and forward. Pus was gained at great depth, and the abscess was incised and drained from there by a rather long and deep incision. All the febrile symptoms disappeared, and the boy was discharged cured June 3, 1889.

Case II.—Samuel Gross, tailor, thirty-three years old, was laparotomized at Mount Sinai Hospital, January 27, 1889, for internal obstruction of six days' standing. Fæcal vomiting was present, with enormous tympanites due to intestinal paralysis. The cause of the obstruction was found in a very long and much distended appendix vermiformis, the apex of which was firmly attached to the under surface of the right half of the transverse mesocolon. Through the loop thus formed about three feet of the ileum had slipped and had become strangulated. Corresponding to the attachment of the apex of the appendix a massive swelling was felt occupying the space behind the colon, and when the adhesion was severed, pus welled up from a small aperture corresponding to the site of the attachment. This led into an abscess cavity which was carefully evacuated. The appendix being removed, the intestines were replaced with considerable difficulty. The patient died an hour and a half after

the operation. (For complete history, see *N. Y. Med. Journal*, May 4, 1889, page 478.)

Case III.—Mr. M. G., aged sixty-two, had been suffering from habitual and very obstinate constipation for years. In May, 1880, profuse diarrhœa set in, and could not be controlled by any of the usual dietetic and therapeutic measures. A grave deterioration of the general condition developed, and the patient lost very much flesh in spite of forced feeding.

August 31st.—Fever set in, and the presence of a painful swelling in the iliac fossa was made out.

September 3d.—The author saw the case in consultation with Dr. W. Balser and Dr. L. Conrad. A large fluctuating swelling occupied the right half of the pelvis, and tympanitic percussion sound was noted in the lumbar region. Two incisions were made—one above Poupart's ligament, another in the lumbar region—and an enormous amount of gas, pus, and fæcal matter was evacuated. Profuse secretion and diarrhœa continued, and the patient died September 22d.

Post-mortem examination revealed a tight cancerous stricture of the ileo-cæcal valve, and an enormous dilatation of the lower portion of the ileum, which resembled thick gut. Large masses of impacted fæcal matter were found in this pouch, which was adherent to the posterior parietal peritonæum, and was freely communicating through a number of ulcerous defects with the abscess cavity.

4. *Rectal Type.*—It is a good rule never to neglect to examine the rectum of a patient suffering from perforative appendicitis. A long appendix may become fixed and perforated in the small pelvis, and an abscess is then apt to develop in close vicinity to the rectum, whence it can be safely opened and evacuated. The objection that fæces might enter the abscess has thus far not been verified by experience.

Case.—August Petry, clerk, aged eighteen, was admitted, November 10, 1887, to the German Hospital with symptoms of perforative peritonitis. General tympanites prevailed, and a tumor could not be felt anywhere, but intense pain was complained of on pressure in the right iliac fossa. The poor state of the patient forbade operative interference, and opiates and stimulants were exhibited. By November 13th the patient had fairly rallied. An examination of the rectum disclosed the presence of a fluctuating swelling corresponding to its anterior wall. An incision evacuated a large mass of pus, and a drainage-tube was placed into the cavity and brought out through the anus. The tube was not borne well. It excited tenesmus, and was repeatedly expelled. As the patient was doing very much better, and the tumor had disappeared, it was left off without ill consequences. The patient was discharged cured November 27, 1887.

5. *Mesocœliac Type.*—To characterize that most serious form of circumappendicular abscess, the walls of which are composed entirely of agglutinated intestines, and which hold no immediate relation whatever with the parietes of the abdominal cavity, the term "mesocœliac" was chosen (from *αἱ κοιλίαι*, the intestines, and *ἐν μέσῳ* between). The abscess is found occupying, as it were, the middle of the peritoneal sac. Hence, to reach and evacuate this form of abscess, the free peritoneal cavity must be opened, and the collection of pus must be reached by separating the adherent coils of gut which inclose it.

We owe the development of the *technique* of the evacuation of these abscesses mainly to McBurney, whose procedure is as follows: A longitudinal incision, as for simple appendicitis, is made parallel to and along the outer border of the right rectus muscle. The abnormal cohesion and resistance of the implicated intestines will point out the site of the abscess. The protruding normal coils of gut should be packed away under a protective bulwark of sponges held *in situ* by the assistants' hands, so that, if the abscess is opened unawares, no pus should soil the healthy peritonæum. Two of the nearest coils are now gently and cautiously separated by gradual traction, exercised by the operator's fingers, until a small quantity of pus is seen exuding. It is desirable to let the pus escape slowly, so as to have ample time to sponge it away as it pours out; otherwise the whole field might be overwhelmed and contaminated by a sudden flood of matter.

Note.—It seems that exhausting the abscess through a small aperture by means of a syringe would be an improvement upon the mopping up by sponges.

As soon as the bulk of pus has been removed, the cavity is wiped out clean with sponges dipped in an antiseptic solution, and now the adherent intestines are still more separated to permit the surgeon to inspect its interior. If the appendix is loose and easily to be got at, it can be removed, but, if it is found closely adherent and very brittle, it is better to remove only so much of it as will come away easily. A good-sized drainage-tube is placed into the bottom of the cavity, which is, in addition, loosely filled with strips of iodoform gauze. These and the rubber tube are brought out near the lower angle of the wound, and the abdominal incision is closed in the usual manner. If the case is progressing well, the packing can be withdrawn on the third day, as by that time protective adhesions will have formed between the adjoining coils of gut. The drainage-tube is to be removed as soon as the secretions become serous and scanty.

C. Chronic or Relapsing Appendicitis and Perityphlitic Abscess.

It was shown how simple catarrhal conditions of the mucous lining of the appendix may lead to more or less complete occlusion of the exit of this viscus. The retention of the secretions will then cause distension and the train of symptoms characteristic of appendicitis. With the diminution of the catarrhal swelling of the mucous membrane, a restitution *ad integrum* will take place. Usually the symptoms produced by this form are mild and tractable. Bland laxatives and opiates, rest in bed, with some form of local applications, generally bring about a lasting recovery.

Where ulcerative processes, prolonged inflammation, or the doubling of the appendix upon itself, have caused the formation of cicatricial matter—hence permanent stenosis of greater or lesser intensity—the recurrence of severe obstructive symptoms will be more frequent, the intervals between the attacks shorter and shorter, and the tendency to the formation of adhesions more pronounced. Thus the very chronicity of the process will yield, in its tendency to the formation of adhesions, a certain protective character.

Should perforation occur, these adhesions fulfill a most important function in preventing general septic peritonitis. The number of relapses of appendicitis may be very great; in one of the author's cases sixteen were counted. With the increase of the cicatricial stenosis, the formation of concretions, and the loss of contractile power of the appendix, the tendency to ulcerative or gangrenous lesions becomes more and more pronounced, and finally culminates in perforation.

As we have no means of ascertaining the exact condition of the appendix, frequent recurrence and increasing severity of the disorder clearly justify an attempt at its removal. The term "attempt" is used here purposely to signify that such endeavors may occasionally be baffled by intricate and close adhesions, which a prudent surgeon may prefer not to disturb for fear of lacerating the gut. It may be said, however, that, should the first attempt fail, a second one may be crowned with success.*

All surgeons admit the occurrence of the spontaneous evacuation of perityphlitic abscesses into an adjoining part of the gut. Occasionally perforations into the bladder, rectum, or even the pleura, have been observed and described. If such an evacuation into the gut is followed by a perfect obliteration of the cavity and fistula, no relapse will occur. Should evacuation be imperfect, inspissation of the retained pus and a temporary dormancy of the acute signs of the process will result, until some local irritation again provokes rapid intumescence, followed by evacuation of the surplus contents of the abscess. This process may be repeated a number of times, as a result of which a thick mass of cicatricial matter will be deposited around the focus. Cases of this order demand surgical interference.

Case.—Miss Caroline D., aged fourteen, had had within two years three attacks of perityphilitis with well-marked ilio-inguinal tumor, which never disappeared completely. On April 24, 1888, Dr. L. Arcularius presented her to the author, who advised an operation. A small immovable tumor could be felt occupying the iliac fossa. On May 1, 1888, an incision was made, and a small cavity of the size of a chestnut was laid open. Its walls consisted of a massive deposit of cicatricial matter, its contents of a putty-like mass of inspissated pus, surrounded by a coating of deciduous granulations. When all the soft matter was scooped out, a narrow sinus was traced to a depth of an inch and a half beyond the bottom of the cavity. The wound was packed, and was kept open with considerable difficulty during the entire summer, small quantities of feculent matter escaping from time to time. In the course of the following winter the tumor gradually shrank away, the discharge dried up, and, the tube being removed, permanent healing took place.

Had the outer opening been permitted to heal, recurrence of the abscess would have probably followed, as closure of the communication with the gut came about with a great deal of hesitancy. The same state of affairs may and does often prevail in abscesses that are evacuated by the surgeon, and in which the outer opening shows a more pronounced tendency to closure than the sinus leading from the abscess cavity to the gut. Thus the presence of a however minute fæcal fistula that has not healed soundly may bring about a number of recurrences in the tract of the old abscess. It stands to reason to say that inadequacy, both as regards the quality and duration of drainage of the abscess cavity, has a most important influence upon the retardation of the closure of the fæcal sinus. Hence the tendency to relapses will be very pronounced in cases where evacuation of the primary abscess took place spontaneously.

Case.—Frank Kennedy, printer, aged twenty-five, had suffered since childhood from a number of attacks of smart pain in the right groin accompanied by fever. In the early part of 1885 he acquired an oblique inguinal hernia of the right side, and was ordered to wear a truss, the pressure of which, if the pad became displaced outward, caused intense suffering, so that he had to abandon its use from time to time. In June, 1885, during a severe attack of fever, an abscess broke open two inches and a half below the anterior superior spine. Since then healing and reopening of the sinus had occurred four times. On March 3, 1886, a dense deep-seated tumor could be felt in the right groin, independent of the hernia, which could be easily replaced. Following the existing sinus, the center of the indurated mass was laid open by a large incision running parallel with Poupart's ligament. At the depth of two inches a globular smooth-walled cavity was exposed, within which, imbedded in frail granulations, a stratified coprolithon of the size of an unshelled almond was found. A channel of the diameter of a goose-quill was seen leading from this cavity inward and downward, into which could be slipped twelve inches of a slender drainage-tube. When water was thrown in through this tube, diluted fæcal matter regurgitated. Under the microscope this matter was seen containing granules of amylum and fat with fat crystals arranged in the shape of sheaves. The wound was kept packed with gauze till March 25th, and was healed, seemingly from the bottom, by April 14th. On November 15, 1886, the fistula reopened, and the proposition was made to the patient to expose the site of the fæcal sinus from within by laparotomy, and to deal with it by extirpation of the appendix or enterorrhaphy. He declined to take the risk, and preferred to wear a tube permanently. Sparse quantities of a feculent, orange-colored serum continued to escape from time to time until the end of 1888, when the tube could not be replaced once, and was abandoned. As it seems, permanent healing then took place.

The proposition made to this patient to close his fæcal fistula by laparotomy and an appropriate dealing with the involved gut, contains the essence of a plan the adoption of which might be necessary in order to bring about the speedy cure of an apparently interminable, most disagreeable, and loathsome ailment. But the necessity for the adoption of such extreme measures must be very rare indeed.

On the whole, it may be said that the recurrence of an evacuated perityphlitic abscess is comparatively rare, and that, if it is due to the presence of a fæcal fistula, its lasting cure can in most instances be effected by prolonged and efficient drainage of the outer wound.

Another cause of prolonged suppuration within and around an incised perityphlitic abscess is the formation of one or more extraperitoneal burrows and cavities, located

* I take the liberty of referring to a verbal communication of Dr. F. Lange, who informed me that he once had to abstain from removing the appendix through an anterior incision. Later on the organ was successfully removed through a posterior wound.

between the several layers of the abdominal wall, which are the direct consequence of inadequate measnres at drainage. The primary cause of the abscess may be eliminated, the perforative aperture of the appendix or gut may long since have permanently closed, and yet frequent relapses of suppuration will keep the patient confined to the bed. How to deal with a case of this kind may be seen from the following history:

Mrs. E. T., aged thirty-two, was operated for perityphlitic abscess by a prominent gynæcologist of this city in the latter part of the summer of 1887. Four weeks after the operation the drainage-tube was withdrawn, and the wound healed promptly, but a reaccumulation and evacuation of pus soon followed, and symptoms of recurrent retention were observed on an average every four or six weeks until January 13, 1889, when, by the same practitioner, bloody dilatation was done with the confident expectation of lasting success. These hopes, however, remained unfulfilled. Up to March 1, 1889, three more recrudescences occurred which were closely observed by the author. Each time symptoms of retention were present, though a large and long drainage-tube was constantly *in situ*, reaching to the bottom of the wound. Circumscribed swellings occurred then once above, another time to the inner side of the sinus, and pus was seen welling up on pressure from the drainage-tube. It was decided to find and remove the cause of this distressing condition by an operation, which was done March 11, 1890, in the presence of Dr. Lange and Dr. Bull, of this city. The tract within which had lain the drainage-tube was exposed to its bottom by an incision nine inches long, and running parallel with Poupart's ligament. Carefully examined, it was found to be soundly and firmly closed at the bottom, no manner of communication existing with the gut, though it was evident that only a thin layer of tissue separated the cavity from the peritoneal sac. On the lateral aspect of the smooth lining of the old drainage track, and not far from the bottom, two minute apertures were seen inosculating, into which the probe passed for a distance of two and four inches, respectively, the longer track leading toward the navel, the shorter upward toward the crest of the ilium. When these narrow tracts were slit up, each of them was found terminating in a small pocket containing granulations and pus. These sinuses were located within the abdominal parietes, between the muscular and peritoneal layers. Unavoidably, the peritoneal cavity was opened in two places, but, as no tumor could be felt within, these apertures were not enlarged. The very large wound was purposely left open, and the dressing consisted in an iodoform-gauze packing. Uninterrupted healing followed, though it took a long time on account of the size of the wound.

June 3d.—The patient was discharged cured, and has remained well ever since then.

Conclusions.—1. Mild, presumably catarrhal, forms of appendicitis require no operative measures, but dietetic and medicinal treatment by opiates, laxatives, rest, and local applications.

2. The more severe and persistent forms of appendicitis may render excision of the appendix advisable, especially if frequent recurrence, with increase of the violence of the symptoms, is observed.

3. Most perityphlitic abscesses hold close relations with one or another of the abdominal parietes. The location of the parietal adhesions of the abscess is to be first ascertained, if necessary, by exploratory laparotomy, and the abscess is to be then incised and drained through the area of adhesion, thus avoiding infection of the sound peritonæum.

4. Perityphlitic abscesses that possess no parietal adhesions and have a mesocœliac situation between free coils of intestine must be reached by laparotomy through the uninvolved peritoneal cavity. Precautions have to be taken not to infect the normal peritonæum.

5. Recurrence of suppuration in the groin, following spontaneous or artificial evacuation of a perityphlitic abscess, may be due either to the persistence of a small fæcal fistula, or to the presence of secondary intraparietal sinuses caused by inadequate drainage and retention.

In the first case prolonged and efficient drainage is to be employed for a long time before resorting to artificial closure of the fæcal fistula by laparotomy and enterorrhaphy or otherwise.

In the second case all sinuses and pockets have to be found by free and careful dissection, and, when they have been slit up and scraped, the wound is to be treated by the open method to effect a sound cure.

ERYSIPELAS

TREATED WITH THE BICHLORIDE OF MERCURY,

AND THE RESULT IN FOUR CASES.

By W. SHROPSHIRE, M. D.,
HUNTSVILLE, TEXAS.

Not having seen any mention of the treatment of erysipelas by the local application of the bichloride of mercury, I desire to give the results of my efforts with the remedy, and hear the opinions of others with a more extended practice than my own, when they have tried it to their own satisfaction. The following report will show the method of application and results obtained:

Case 1. *March 23, 1889.*—I was called to see Minnie R., aged one year, who, two weeks prior to that date, had received a scald on the right leg, which healed cleverly till a week subsequent, when erysipelas set in and spread rapidly up the leg and over the thigh, etc. The family physician was called in and prescribed a four- or five-per-cent. aqueous solution of carbolic acid to be continuously applied to the inflamed area, which was done till I saw her, when I found the child suffering from carbolic-acid poisoning, and the erysipelas having spread over the whole of the thigh, half the nates, and a portion of the abdomen, and was rapidly spreading. It was of the variety which has a vesicular eruption over the inflamed area. Her temperature was 102·8°, pulse 170, weak and thread-like. I prescribed quin. sulph., gr. ¾; tinc. ferri. chlor., ♏ij, every three hours, and the application of a saturated solution of ferri sulph. locally by keeping a cloth wet with the solution and applied to the inflamed area.

24th.—Temperature, 102·4°; pulse, 160 and fair; symptoms of carbolic-acid poisoning gone; inflammation rapidly spreading and looking quite angry, and she was quite restless through the night. The iron and quinine internally were continued, and the local application was changed to hydrargyri chlo. corros., ammon. chlo., āā gr. vijss., dissolved in one quart of water, applied by keeping a cloth wet with the solution and applied to the inflamed surface, especially the spreading edges.

25th.—Temperature, 101°; pulse, 140. Rested some during

the night; ate some. Inflammation spreading only in the inguinal region, where the application was imperfect, and subsiding elsewhere. Treatment continued.

26th.—Temperature normal; inflammation subsiding rapidly; no spread since last visit. Treatment was discontinued on the 27th, and tonic of ferri. sulph., quin. sulph., āā gr. ¾; acid citric, gr. jss., ter die, substituted. Four days later I saw the child in the yard playing with others, apparently perfectly well.

Case II. *July 9th.*—Was called to see John G., aged thirteen years. The day before he had noticed an inflammation on the posterior aspect of the shoulder at the margin of the axilla and soon became feverish, both spots growing rapidly worse. I found him with a temperature of 104·8°, as I supposed, partially due to malarial complication, and an area of about fourteen or sixteen square inches of erysipelatous inflammation in the situation mentioned, belonging to the same type as No. 1, that characterized by a vesicular eruption. I prescribed quin. sul., gr. v, every four hours, and the topical application of a 1-to-2,000 solution of the bichloride of mercury as applied in Case I.

10th.—Temperature, 105°; pulse, 134. Area of inflammation greatly increased, and a new place on the elbow of the same side. I ordered acetanilide, gr. iv, not to be repeated; continued the quinine in five-grain doses, and changed the bichloride solution from 1 to 2,000 to 1 to 1,000 and applied as before.

11th.—Temperature, 101·4°; patient bathed in perspiration and the inflammation not spreading but subsiding. Treatment was continued.

12th.—Temperature, 99°. Inflammation greatly diminished. Treatment was discontinued on the 13th, and a tonic of iron, quinine, and strychnine was ordered for a week, before which time the boy came to my office apparently quite well.

Case III.—Mr. K., about twenty-two years old, called at my office showing about half of his forearm covered with erysipelatous inflammation of the non-vesicular variety, which had begun the day before at a tick bite near the wrist. I prescribed the bichloride of mercury, gr. viij to one pint of water, to be applied as in the former cases. On the following morning he complained of considerable pain from the application of the solution—so much so that he could not sleep the night previous, but there was no spread of inflammation. I ordered morph. sulph., gr. vij to the pint of solution, to be applied as before. Two days later he showed me his arm, and where the inflammation had existed there were quite a number of pustules very much like those caused by the local application of ol. tiglii. I ordered it rubbed with carbolized vaseline, and heard nothing more of the case.

Case IV.—Mr. M., aged about thirty-five, called at my office and showed an area of eighteen or twenty square inches of erysipelatous inflammation on his right forearm, with red lines running from the inflamed area toward the body. It was of the non-vesicular variety. I prescribed the bichloride-of-mercury (1 to 1,000) aqueous solution, to be applied locally, as in other cases. Six hours later I was called to see him, when he complained that the medicine burned too severely to be borne, and I ordered a solution of sulphate of morphine, seven grains to the pint, and heard nothing more of the case till three days later, when he showed me his arm, then apparently perfectly healthy.

Cases III and IV are reported from memory, but Cases I and II are taken directly from my case register. I treated two other cases with the same remedy, but one was never seen after it was prescribed for; and the other was so complicated by other diseases that it is unworthy of being reported.

Aside from the clinical evidence of these cases, we have certain well-established facts, and good reason for the treatment of erysipelas with the topical application of the bichloride of mercury. That erysipelas is an inflammation of the skin, and the work of a specific micro-organism, is generally acknowledged; and that the bichloride of mercury is one of the most powerful germicides is equally as generally conceded. With these facts in view, the rational treatment of the disease is to apply the remedy to the cause; so the question is how to apply it in sufficient quantity to kill the micro-organisms and not hurt the patient or endanger his life; and I think it is fairly solved by the cases reported.

It may be advisable to remove the sebum off the skin with soap and water before applying the solution of bichloride; but, in the majority of cases, the corrosive nature of the drug is, I think, sufficient to remove the sebum without the use of any adjuvant. In addition to the benefit of the bichloride, in the above-given plan of treatment, the continued application of cold water to the heated and inflamed surface relieves the suffering and checks the inflammatory process. I hope others will try the treatment and report the result of the same, for if the remedy proves as efficient in all cases as it seems to have done in those here reported, it certainly is to be preferred to the necessarily very painful and somewhat dangerous treatment by hypodermic injections of an aqueous solution of carbolic acid, from the fact that it is both less dangerous and painful, and, when compared with other treatments, its efficacy places it first. I will suggest a strength of 1 to 2,000 for young children and 1 to 1,500 for adults as probably the best to use.

THE STANDARDIZATION OF GALENICAL PREPARATIONS.*

By SOLOMON SOLIS-COHEN, M. D.,
PROFESSOR OF CLINICAL MEDICINE AND APPLIED THERAPEUTICS, PHILADELPHIA POLYCLINIC.

The question of the uniformity and reliability of the medicinal preparations employed in the treatment of disease is one of considerable importance to physicians and their patients. So far as it is practicable, it is certainly desirable that tinctures, fluid extracts, and the like, should represent a definite strength not merely of the crude drug, but of those constituents of the drug upon which its therapeutic and toxic activities depend. We have all experienced the embarrassment which attends the use of a preparation of unknown power, for, on the one hand, our dose may be too small to accomplish the desired result, and, on the other hand, it may be so large as to be dangerous. So long as the Pharmacopœia of the United States fails to prescribe a uniform and exact standard for such drugs as opium, belladonna, aconite, nux vomica, conium, and others which might be mentioned, this danger and uncertainty must remain. In the case of a drug like opium, in which the phar-

* We greatly regret that our engagements prevented the publication of this article before the time of meeting of the Pharmacopœial Convention. Doubtless, however, the Committee of Revision may yet be able to give due consideration to its arguments, and certainly the medical profession must feel interested in them at all times.—Editor.

macist is allowed to use his discretion as to whether it shall represent twelve per cent., or anything between that and sixteen per cent. of its most powerful alkaloid—a range of variation of twenty-five per cent. if we take the highest figure, and of thirty-three per cent. if we take the lowest figure—it is obvious that the physician is unable to prescribe an accurate dose, and must perform a series of tentative experiments with each new preparation that is ordered. Not only will there be a different therapeutic and toxic value to the preparations obtained from different druggists, but unless each druggist adopts for himself a definite standard, be that the highest or the lowest required by the Pharmacopœia, preparations obtained from the same druggist at different times will likewise vary.

It would seem, then, the obvious duty of the Pharmacopœial Convention to adopt one definite morphine strength for opium preparations, and for physicians to demand of druggists absolute conformity with the pharmacopœial requirements. But as regards opium we are much more fortunate than with other drugs possessing equally dangerous properties, if given in excessive doses. With opium, at least, we can guess within thirty-three per cent. of its strength, but with belladonna, to take but one example out of many, we can not guess even that.

In a paper recently read before the Philadelphia County Medical Society, Dr. H. H. Rusby states that the percentage of total alkaloids in belladonna leaves may vary as much as two hundred and fifty per cent., and that the physical properties of the drug give no indication of its alkaloidal value, some of the worst-appearing leaves giving the best assay.

Now it is true that the physician who desires to produce an atropine effect can attain his object most readily and satisfactorily by administering a salt of the alkaloid; but atropine does not represent belladonna. There are cases of daily occurrence in which we desire to administer the galenical preparation and not the alkaloid. It is in these cases that the constant uncertainty concerning the activity of the preparation employed leads to the double danger of failing to secure the effect desired if we use a small dose, and of poisoning our patient if we use a large one, with the preparation unexpectedly more active. It is reasonable to suppose that whatever constituents of the drug give it its therapeutic powers will be found associated in about the same proportion, and that the total alkaloidal strength will represent the total therapeutic value. It certainly will represent the total toxic activity. It is further evident that what the physician is concerned with is, not the quantity of crude drug to be used by the pharmacist, but the strength of the finished product which he prescribes. That, with one lot of leaves, one fourth of the quantity of crude drug prescribed by the Pharmacopœia will produce a fluid extract or tincture of sufficient therapeutic activity, or that, in another case, four times the pharmacopœial quantity will be required, is a matter of absolutely no consequence to physicians. What they have a right to demand of the Pharmacopœial Convention and of the intelligent pharmacists who will assist in its deliberations, is to lay down a broad principle that in every possible case the preparations to be prescribed by physicians and taken by patients shall have a uniform and definite strength; and it will then become the duty of the Committee on Revision, with the aid of its experts, to ascertain the best method of putting this principle into practical application. But it must be distinctly understood that the standard applies to the finished official preparation, for this is what the physician prescribes. Of what advantage is it to know that tincture of nux vomica represents so many parts in a hundred of a drug whose alkaloidal strength has a range of variation of fifty per cent? And as this variation is incurable, it is obvious that parts in a hundred must be varied in an inverse ratio to produce a preparation of standard strength. The fact that a certain firm of manufacturing chemists—it may be with far-sighted business instinct, it may be with a professional pride and honor which should not be unexpected from those having such intimate relations with the medical profession—has, without waiting for the Pharmacopœial Convention, instituted for itself a series of elaborate and expensive experiments, and put upon the market preparations of guaranteed strength, such as the Pharmacopœia should require from all manufacturing houses and from all retail pharmacists; this fact—humiliating as it is to scientific men, who should not have allowed manufacturers to take the lead in so important a reform—should certainly not act prejudicially to the adoption of the principle contended for. On the contrary, the writer, who has a very wholesome aversion to indorsement of any kind of patented or trade-marked preparations or appliances, would feel that he was doing an injustice to the enterprise and scientific spirit of Messrs. Parke, Davis, & Company, if he did not mention that house with due credit and praise, and express the satisfaction which he has derived from the use of their standard preparations in contradistiuction to the disappointment which has often attended his use of the uncertain preparations of the Pharmacopœia. As a matter of course, since the point has been raised, the name which this house has applied to its line of assayed preparations should not be admitted into the Pharmacopœia any more than such names as "antipyrine," "antifebrin," "salol," and the like; though there is this difference to be observed to the credit of our American manufacturers: that their names are not trade-marked, while those of the German houses, whose preparations are so extensively sold in this country, are, under the laws of the United States, which afford permanent protection to trade-marks, equivalent to a perpetual patent right.

The principle advocated by those who desire to have uniform standards of strength of pharmacopœial preparations is so obviously correct that it is hard to avoid repetition and superfluous iteration in its presentation; the mere statement of it should suffice, without argument.

The time is near at hand for the assembling of the Pharmacopœial Convention, and it is the duty of physicians to consider the subject very carefully and to express their views publicly, in order that a due weight of professional opinion may be brought to bear upon the deliberations of the convention; to secure the removal of the conditions of uncertainty which are not only a discredit to the

two learned professions of medicine and pharmacy, but, in addition, always a disadvantage, and sometimes a danger to the community at large.

Correspondence.

LETTER FROM LONDON.

Hospital Administration Inquiry.—The Scheme for a New University for London.—The British Medical Association Meeting at Birmingham.—Public Exhibitions of Hypnotism.

LONDON, *June 2, 1890.*

A SELECT committee of the House of Lords is at present engaged in inquiring into the mode of administration and management of the leading hospitals of London. One of the chief ostensible reasons for the appointment of the committee was the alleged abuse of the out-patient departments by the public, and there can be no doubt that there has been for some time a good deal of outcry in the ranks of the profession on this subject. That the hospitals may be and occasionally are abused there can be but little doubt, but I am inclined to think, from a not inconsiderable experience, that there is a great deal of exaggeration on the subject; what is really wanted is some reform in regard to the way that letters of recommendation are given by the subscribers to the hospitals, as most of the "ineligibles" are attending with subscribers' letters. If, as the outcome of the present inquiry, subscribers' letters should be altogether abolished, the committee will not have sat in vain. Another matter in which a good result may be expected is in putting a stop to that indiscriminate starting of special hospitals from which we have suffered most heavily and are still suffering. It is really the special hospitals which are the greatest sinners in competing with the general practitioners, for they are often officered by men of no very high standard of professional morality, who would not hesitate to transfer a patient who could afford to pay to their own houses or see him in a private room at the hospital, without giving one moment's thought to the fact that they were deliberately robbing another man of a patient. If there is a danger that the inquiry may imperil the material at present at the disposal of the general hospitals for clinical purposes (and no doubt this danger exists) there is, on the other hand, the possibility that it may be the means of opening up to us the immense resources of our workhouse infirmaries for that purpose—a thing which many of us have been longing for for a considerable period and which now seems to be coming within the domain of practical politics. Already we have the fever hospitals made available for clinical purposes in a somewhat restricted sense, and at the present moment the post-graduate course includes a weekly visit to one of the largest of the London workhouse infirmaries.

We are rapidly approaching a settlement of the question which has so long been agitating us—viz., how to provide an attainable degree in medicine for our London students; the existing University of London has been given the chance of remodeling itself so as to enable this to be accomplished, and warned that if it does not do it it will be made to stand on one side while Parliament takes the matter in hand; it can be readily understood, therefore, that the university has aroused itself and is making a very real attempt to provide a solution of the difficulty that will be agreeable to all parties. One of the chief difficulties is that there are two teaching bodies—viz., University College and Kings College—which are equipped for giving instruction in all branches of education, and that they claim a distinct position in the new university, while, as regards their medical faculty, the nine other medical schools strongly object to any privileges being granted to the two bodies named in respect of their medical sections which are not also granted to all alike, and in this they are strongly supported by the Colleges of Physicians and Surgeons; the latter bodies are trying to obtain a joint control of the examinations with the university, and there is evidently much to be said in support of their contention. It is expected that the university will promulgate a scheme in the course of a very few days, and it is certain that the very great desire on the part of all concerned to obtain a settlement of this vexed question will secure for it a most favorable consideration.

Our societies have almost concluded their sessions; the Clinical and Pathological have held their last meeting, and the Royal Medical and Chirurgical will hold its last meeting next week, and, notwithstanding the inconvenience experienced at the commencement of the session by the new premises of the latter society not being ready for occupation, the amount of work performed by the leading societies will not be less than that of past years, though there have not been any great discussions such as those on tubercle bacilli or Charcot's joint disease, only to cite two of the more recent instances; two committees are at work, however, which will no doubt supply material for excellent discussions at future meetings. The Clinical Society has a committee at work on the period of incubation of the various infectious disorders—an inquiry which was really undertaken more than ten years ago, but somehow was allowed to lapse and was practically re-undertaken a little more than a year ago. Dr. Dawson Williams, who is the secretary and the moving spirit in it, has given notice that the report will be ready for presentation at an early meeting of the next session. The other investigation is undertaken by the Royal Medical and Chirurgical Society and is on the health resorts of Great Britain; the leading men on the committee are Dr. Hermann Weber, Dr. Dickinson, Dr. Mitchell Bruce, Dr. Penrose, and Dr. A. E. Garrod, and it is believed that their report will be ready for presentation during the forthcoming session.

Our medical colleagues in Birmingham are making great preparations for the meeting of the British Medical Association, which is to be held there in August under the presidency of Dr. Wade, and the programme which has already been put forth shows that the meeting will not be behind any of its predecessors in scientific interest. There had been some talk of holding the meeting this year in London, where the association has not been received, I think, for nearly twenty years, but the agitation last autumn which terminated in the resignation of some seventy members caused the leaders of the association to go elsewhere, though the actual loss to the association was exceedingly small and has since been further lessened by the return of a considerable number to the fold. I am told that these disputes and secessions are periodical, that the discontented persons always return sooner or later, and that this is a far smaller secession than either of its two predecessors. The number of members of the association is now greater than it has been at any previous time.

A protest is being raised—not before it was wanted—against the spread of hypnotic experiments in public performances. An anonymous writer in a medical journal last week put it very well when he said: "Hypnotism is apt to be a dangerous mental poison, and as such it needs to be fenced round with as many restrictions as the traffic in other kinds of poison. Narcotics of any kind are not to be handled by the ignorant, and are liable to reckless abuse by the feeble in mind or body."

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, JULY 5, 1890.

SOME UNUSUAL MODES OF INFECTION WITH SYPHILIS.

An examination of the medical literature of the past would show a long list of sources of mediate infection with syphilis; but to this already extensive and varied collection Dr. R. W. Taylor has added a number of novel and striking ones, the details of which he has presented in an interesting paper read at the Fourth Annual Meeting of the American Association of Genito-urinary Surgeons, and published in the June number of the *Journal of Cutaneous and Genito-urinary Diseases*. From this article it appears that the popular and apparently innocent gum-chewing craze may be accompanied by the hidden danger of syphilitic infection. A lady who had become infected with syphilis from a towel which had been secretly used by her maid subsequently had a sore mouth and tongue, and while in this condition she got into the habit of using chewing-gum. On two occasions she had temporarily placed her bolus on some article of furniture, and it had been taken up by mistake and chewed for some time by another lady. This second lady had abraded her lip while brushing her teeth a short time before, and on this wound a typical indurated chancre appeared, accompanied by marked enlargement of the submaxillary and cervical glands. In due time roseola and rheumatoid pains ushered in the secondary period of syphilis. All other possible sources of infection had been very carefully excluded.

In many cases of syphilis it is very difficult to trace the source of infection, even when the patient is truthfully endeavoring to assist the physician in this task; and this difficulty is often owing to the fact that the questions asked do not elicit the desired information. We must sometimes, with tact and prudence, inquire concerning certain unnatural practices, about which some men have no shame, while others are very sensitive. The necessity of this is shown by a case in which an eminent practitioner pronounced a man free from syphilis because he had not been exposed in the usual way for fully two years, and yet, on examining into his history more thoroughly, it was ascertained that, while going home one night slightly under the influence of liquor, he had been accosted by a stranger, who led him into a secluded spot, where he performed upon him one of these unnatural practices. Two weeks later three excoriations appeared on the penis, and later on developed into indurated nodules, and the secondary manifestations of syphilis appeared in due time. Many men seem to consider that indulgence in these unnatural practices does not come under the head of exposure to syphilis, and so they often unintentionally mislead their physician. There is a class of men, chiefly young—although older ones are among their number—who are the victims of sexual perversion, and who grant to and receive from men libidinous favors in revolting and unnatural practices. They patrol dark and unfrequented streets, and prove a constant annoyance to the police after dark by "hanging around" our public parks and haunting the public places of urination, and also the water-closets in hotels. In December, 1888, Dr. Taylor presented to the New York Dermatological Society one of these men, who was suffering from a well-marked chancre of the tonsil and general syphilitic manifestations. He had undoubtedly received his infection from a man who had a hard chancre, and there is no knowing how many men he had infected before his tonsillar chancre caused such pain and uneasiness as to disable him for his favorite pursuit. In any future legislation—if there ever is any—for the prevention of venereal diseases in this country or State, these persons should be prominently remembered. The members of this promising fraternity are well known to the police, who, having as a rule an antipathy to them, keep a sharp eye upon them, causing them to keep moving, and in every possible way interfering with their beastly pursuits.

A much less revolting but still very important mode of syphilitic infection next received the author's attention—viz., by post-mortem examinations on those who have died while the disease was still active. Two very striking cases were related, and they certainly point to the importance of such a mode of infection.

The cases cited were both observed in physicians. In the first one the physician held an autopsy on a person who had died of syphilis maligna and tuberculosis, eight hours after death; and during the examination he broke the end of one finger-nail and tore the flesh. The raw surface healed in five days, but on the fifteenth day after the autopsy redness and a slight fissure developed at this spot, and within two weeks there was an exuberant vegetating chancre, with epitrochlear and axillary adenopathy. In forty-five days general syphilitic manifestations appeared. While he had been attending the patient there had been no lesions which might possibly have conveyed syphilitic infection, and he was sure that he had not been exposed to syphilis in any manner for at least eight weeks prior to the autopsy. In the second case the unfortunate victim was a healthy man, twenty-six years of age, of temperate habits and having a good family history. On November 29, 1887, he made an autopsy, nine hours after death, of a prostitute who had died of cerebral apoplexy. She had scars on her body, which were no doubt syphilitic lesions. At the time there was a small crack just under the third finger-nail, and this he covered with collodion. On December 21st he performed another autopsy, five hours after death, upon a man who had died of acute alcoholism with cirrhosis of the liver and kidneys. He also had a fracture of the jaw with a large and very foul external wound. About three or four days after this second autopsy a fungous growth appeared about the nail on the physician's third finger, and this would not heal, although various methods of treatment were adopted. On January 23, 1888, he took a Turkish bath, and on the following day felt feverish and much depressed. In

the evening a rash appeared on the arms and hands. Thinking that he was suffering from septic matter absorbed at the time of the second antopsy, he sought advice, and was greatly surprised to learn that he had been infected with syphilis. All other sources of infection were carefully excluded. He had evidently been infected at the time of the first autopsy, so that fifty-four days elapsed between the infection and the systemic outburst. This length of time would fully cover the two classical periods of incubation observed in the development of syphilis, while the time between the second autopsy and the evidence of infection was far too short for syphilis. It was worthy of note that both these autopsies had been made within a comparatively short period after death; and it is probable that, if infection does occur in this way, it is only when the examination is made soon after death, and before cadaveric changes have taken place, for the latter probably destroy the syphilitic virus.

Dr. Taylor related the histories of cases showing syphilitic infection from a caustic-holder, a handkerchief, a bathing-suit, a syringe, a pair of drawers, a whistle, a tongue-scraper, a razor, a pillow, etc., and called attention to the liability of such infection from water-closets. He thought the profession was far too skeptical in regard to this source, for he had seen many cases of hard chancre the bearers of which had told him that they frequently renewed their dressings and inspected the diseased organ while sitting upon a water-closet seat. Then there were cases of mucous patches and condylomata lata of the scrotum which, unless great care was exercised, must come in contact with the water-closet seat. There was also a method of infection that had not before been described, but which the author had observed in at least a dozen cases. It generally occurred in this way: A man, fearing to contract the venereal disease, or for other reasons, contented himself with digital fondling of the female genitals. In this way his fingers might become soiled with the secretion from syphilitic excoriations, and the virus might be transferred from his fingers to some other part of his body—generally by scratching or picking. In this way chancres might be produced on the tip of the nose, the chin, the cheek, the neck, or arm. It was highly probable that many chancres about the face in men originated in this manner.

The author concludes by pointing out the necessity for greater care on the part of physicians in explaining to their syphilitic patients how they may become disseminators of infection, and the means to be taken to prevent that great disaster to others.

MINOR PARAGRAPHS.

POTASSIUM TELLURATE IN THE NIGHT-SWEATS OF PHTHISIS.

In the *Wiener klinische Wochenschrift* for June 5th Dr. Edmund Neusser relates his experience with potassium tellurate as a remedy for the night-sweats of consumptives. He used it in the form of a pill, giving at first 0·02 gramme (about a third of a grain) at a dose. In most of his cases this proved sufficient, but a few patients began to sweat again after a time, and with them he doubled the dose, generally with good results. In but few instances were any toxic effects observed; even with doses of a grain, it was only after their prolonged use that anything of the kind occurred, and then the symptoms were only those of moderate disturbance of digestion. An objection to the employment of the remedy, however, is the fact that it imparts an intense garlicky odor to the breath, but generally this is not perceived by the patient, although two of the patients complained of a sulphurous or camphoraceous odor of the eructations.

WILLIAM CULLEN AS A STUDENT.

In the last number of the *Asclepiad* the editor, Dr. Benjamin Ward Richardson, gives us an entertaining and instructive article entitled William Cullen, M. D., F. R. S., and the Growth of Physical Medicine, illustrated with two portraits of the great nosologist. In his youth Cullen was an exceedingly studious and discreet person. Speaking of him at the age of twenty, when he was employed in an apothecary's shop, Dr. Richardson says of him: "Let the subject of conversation with him be one on which he has little or no knowledge, he will listen and take no part; but speak to him at some subsequent period on the same subject, and beware, or he will confound you with his information."

THE LADIES' HEALTH PROTECTIVE ASSOCIATION OF NEW YORK.

We have more than once spoken of the good work done by this energetic association, and the appearance of its report for the years 1888 and 1889 reminds us of its wide field of operations and of their value as labor supplementary to that of the sanitary officials. The report deals with gas-houses, slaughter-houses, manure and stable refuse, street-cleaning, school hygiene, the Croton water, women as factory inspectors, police matrons, tenement houses, public sewers, etc.—not in a prolix or tedious way, but with the utmost brevity consistent with the importance of those subjects and with a freedom from querulousness that is very commendable.

THE INTERNATIONAL ATLAS OF RARE SKIN DISEASES.

We have received parts i and ii of this very valuable publication from the American publishers, the J. B. Lippincott Company, of Philadelphia. Reserving them for further mention, we will simply note that the work is edited by Mr. Malcolm Morris, of London; Dr. P. G. Unna, of Hamburg; Dr. H. Leloir, of Lille; and Dr. L. A. Duhring, of Philadelphia; that the text is in the English, French, and German languages; that two parts are to be issued annually; and that the work is to be had in this country only of the Lippincott Company, and only by subscription.

"ORISTRY."

According to the *Boston Medical and Surgical Journal*, Dr. J. L. Williams, of Boston, proposes the adoption of this term to signify the rapidly widening specialty of the dental and oral surgeon. The word is compounded of the initial part of *oral* and the terminal part of *dentistry*.

SPECIAL BERLIN CLINICS FOLLOWING THE CONGRESS.

A correspondent informs us that many of the professors and *Docenten* of the university intend to hold special courses of from three to four weeks' duration immediately on the close of the Tenth International Congress. He adds that strangers will

find the varions announcements on the bulletin-boards of the Charité Hospital and the University Clinics.

A NOVEL FORM OF MEMORIAL.

A piece of ground for athletics, of twenty-seven acres, on the banks of the Charles River, has been presented to Harvard University by Mr. H. L. Higginson, of Boston. The field will be known as the Soldiers' Field, and will contain a memorial in honor of seven friends of the donor, who died in or as a result of the War of the Rebellion. One of these seven was that rare and true man, Dr. Edward B. Dalton, for many years the Sanitary Superintendent of the New York Board of Health.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 1, 1890:

DISEASES.	Week ending June 24.		Week ending July 1.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	7	1	11	5
Scarlet fever	33	4	34	10
Cerebro-spinal meningitis	0	0	1	0

The Honorary Degree of LL. D. has been conferred by Lafayette College on Dr. Ezra M. Hunt, of Trenton, N. J., and by Yale University on Dr. Francis Delafield, of New York.

Change of Address.—Dr. Thomas Linn, from Paris, France, to No. 16, quai Masséna, Nice.

The Death of Dr. Edward Malone, of Brooklyn, occurred on June 16th. The deceased, who was fifty-two years old, was born in Ireland, but came to this country while yet a lad. He was educated in Paris and New York. In the late war he served with the Eleventh Brigade, New York State Volunteers.

The Death of Dr. Gustavus A. A. Krehbiel took place at his home, in New York, on the 17th of June, when he was forty-nine years old. He was a native of Bavaria, a graduate of the University of Munich, and for a time a practitioner in Vienna. He came to this country about fifteen years ago, and took a high position as a physician.

The Death of Dr. Willis F. Westmoreland, of Milledgeville, Ga., is announced as having taken place on Friday, June 27th, at the age of fifty-two. The deceased was one of the founders of the *Atlanta Medical and Surgical Journal*, and for many years a member of the faculty of the Atlanta Medical College. During the late civil war he served on the medical corps of the Confederate Army.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending June 28, 1890:*

Page, John E., Berryville, Va.; Kennedy, Robert M., Pottsville, Pa.; Whitfield, James M., Richmond, Va.; Stone, Lewis H., Litchfield, Conn., commissioned assistant surgeons in the Navy.

Atlee, Louis W., Assistant Surgeon. Detached from the U. S. Steamer Marion, and granted three months' leave.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending June 21, 1890:*

Gassaway, J. M., Surgeon. When relieved at Cairo, Ill., to proceed to New Orleans, La., and assume command of the Service at that station. June 4, 1890.

Stoner, G. W., Surgeon. Granted leave of absence for three days. June 18, 1890.

Wasdin, Eugene, Passed Assistant Surgeon. Granted leave of absence for fourteen days. June 5 and 10, 1890.

White, J. H., Passed Assistant Surgeon. To proceed to Savannah, Ga., on special duty. June 9, 1890.

Heath, F. C., Assistant Surgeon. Granted leave of absence for fifty-eight days. June 10, 1890.

Magruder, G. M., Assistant Surgeon. Granted leave of absence for twenty days. June 2, 1890. Ordered to examination for promotion. June 5, 1890.

Woodward, R. M., Assistant Surgeon. Relieved from duty at Chicago, Ill., to assume command of Service at Cairo, Ill. June 4, 1890.

Condict, A. W., Assistant Surgeon. Upon expiration of leave of absence, to report to medical officer in command at Chicago, Ill., for duty. June 4, 1890.

Resignation.

Heath, F. C., Assistant Surgeon. Resignation accepted by the President, to take effect August 31, 1890. June 10, 1890.

Society Meetings for the Coming Week:

Tuesday, *July 8th:* Medical Societies of the Counties of Chautauqua (annual), Clinton (semi-annual—Plattsburg), Greene (quarterly), Jefferson (semi-annual—Watertown), Madison (annual), Oneida (annual—Utica), Ontario (annual—Canandaigua), Schuyler (semi-annual), Tioga (semi-annual—Owego), and Wayne (annual), N. Y.; Norfolk, Mass., District Medical Society (Hyde Park).

Wednesday, *July 9th:* Tri-States Medical Association (Port Jervis, N. Y.); Franklin, Mass. (quarterly—Greenfield), Hampshire, Mass. (quarterly—Northampton), and Worcester, Mass. (Worcester), District Medical Societies.

Thursday, *July 10th:* Medical Society of the County of Fulton (semi-annual), N. Y.

Saturday, *July 12th:* Worcester, Mass., North District Medical Society.

Letters to the Editor.

NITROGLYCERIN IN GAS POISONING.

1519 John Street, Baltimore, *June 24, 1890.*

To the Editor of the New York Medical Journal:

Sir: I have just successfully treated another case, the patient being almost moribund, of poisoning by illuminating gas with the subcutaneous injection of nitroglycerin, $\frac{1}{100}$. The symptoms were not quite so threatening as in the case I described in your issue of October 26, 1889, yet sufficiently so to be alarming, and the result was fully as prompt and happy as in the former case.

I have observed the report of three other successful cases by this treatment, which is surely sufficient to attract the attention of medical men likely to meet with such cases, and to induce them to give it a trial.

The suggestion, made by Dr. F. X. Dooley, of Washington, D. C., in your issue of February 8, 1890, that this treatment should be embodied in our visiting lists, is an excellent one, and should be acted on.

In my paper of October 26, 1889, I stated that the idea was original with me and that, to my knowledge, the remedy had not been used previously for the treatment of such cases. Since the publication of my paper Dr. Crossland, of Zanesville, Ohio, has published a paper in which he states he made use of the same treatment some months before I did. I do not wish to detract in the slightest from Dr. Crossland's merit, but I do say that the idea was entirely original with me and that I promptly published my success for the benefit of my brother practitioners, thereby eliciting Dr. Crossland's case, which otherwise would in all probability never have been given to the profession.

William C. Kloman, M. D.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of May 1, 1890.

The President, Dr. Alfred L. Loomis, in the Chair.

This meeting was devoted to the discussion of the Relation of Peripheral Irritations to Disease, continuing the consideration of the subject adjourned from the stated meeting of March 20th.

The Relation of Diseased Conditions in the Upper Air Passages to So-called Nasal Reflexes.—This was the title of a paper by Dr. F. H. Bosworth. He did not agree with an ancient writer who had believed that all diseases came from the nasal passages, neither did he believe that the nose was absolutely the direct cause of a large number of diseases which were now recorded in the category of nasal reflexes. Furthermore, he thought it was still an open question whether these diseases, when met with in connection with intranasal disorders, should properly be classed as reflexes. It was certain that many of the affections termed reflex must be regarded as directly symptomatic. As to the question of hay fever and asthma, he did not believe that intranasal disease was the cause of every case of these two diseases. The position taken by the speaker on this question, briefly stated, was as follows: First, that the special morbid lesion which gave rise to a paroxysm of perennial asthma was a dilatation of the blood-vessels which circulated in the mucous membrane lining the bronchial tubes, the result of vaso-motor paresis. This vaso-motor paresis differed from inflammation in that, while constituting apparently its first stage, it showed no tendency to go farther. Muscular spasm, therefore, according to the old teaching, played no part whatever in producing an asthmatic attack. Again, there were two predisposing causes of asthma: First, that condition of the general system which we called neurosis, under the influence of which an individual became liable to vaso-motor disturbances in one portion of the body or another. This the speaker regarded as a good definition, from a pathological point of view, of what was called neurosis. So far as clinical observation taught, the one pathological lesion which characterized the direct manifestation of a neurosis was a vaso-motor paresis in one portion of the body or another. In asthmatics this vaso-motor paresis involved the blood-vessels which circulated in the mucous membrane of the bronchial tubes. The second predisposing cause of asthma was a chronic inflammatory process involving some portion of the upper air-tract. In chronic inflammation the prominent feature was vascular dilatation. The whole mucous membrane of the upper air-tract was very closely and intimately related. A hyperæmia of the blood-vessels of the nose showed a marked tendency to be followed by a similar condition of the mucous membrane of the bronchial tubes. This was necessarily a corollary of what was now recognized as the great respiratory function of the nasal passages, by which the temperature and moisture of the inspired air were nicely regulated and adjusted before its entrance into the bronchial tubes. Asthma, as before remarked, was not in all cases caused by an intranasal condition, but an intranasal morbid condition played an exceedingly important part in its development. In the author's original paper—Asthma, with an Analysis of Eighty Cases—forty-six were reported as cured and twenty-six improved, the treatment being largely intranasal. Now, if out of eighty cases forty-six could be cured and twenty-six improved by the local treatment of the nose, there could be no question that we had established the fact that a very large majority of cases, if not all, were dependent upon an intranasal lesion, and by this dependence he did not mean cause, but that the two affections were so closely related that the asthma could be very materially affected and controlled by medication to the nose. As regarded hay fever, this was considered as practically one and the same disease with asthma, and was to be treated in the same way. In regard to certain nervous diseases, such as epilepsy, he had seen nothing in his own practice which warranted the belief that that disease should be looked upon as a nasal reflex. He believed that an intranasal condition was capable of proving a marked source of irritation in any of the nervous affections, the removal of which would modify the symptoms, but that epilepsy had ever been cured by intranasal treatment was, he thought, open to very serious question. Of chorea, he had only known of three cases which had been sufficiently long under treatment to warrant the statement that they had been permanently relieved by intranasal treatment. He did not want to be understood as saying that there was any connection, reflex or otherwise, between chorea and disease of the upper air passages. The good results in these cases could be explained by the fact that the removal of the morbid conditions in the air passages of young patients was often followed by marked improvement in the general health.

Reflex Chorea.—Dr. A. Jacobi, in the course of his remarks on the relation of this trouble to peripheral irritations, thought that quite a large number of cases of chorea minor were due to cerebral lesions, and had more or less pronounced forms of epilepsy complicating them. Other cases might result from apoplexy, tumors, cysts of the brain, diseased cerebral arteries, inflammatory conditions of the spinal cord, sclerosis, emholisms, and so on. Then blood diseases—such as rheumatism, anæmia, nerve inflammations, disorders of digestion or the sexual apparatus, fissures of the anus, or cicatricial contractions—might be looked upon as entering into the causation of chorea minor. It was possible that cases following pericarditis were brought about through reflex action. Others might be due to nasal irritation. Many children developed a train of slight symptoms which were put down simply as bad habits and for which they got punished until the persistency and aggravation of the symptoms led to a proper diagnosis. Some of these patients would be found to be suffering from a nasal catarrh. Many of these got better in warm weather and worse in winter. Looking carefully at such children, it would be seen that there existed a number of symptoms common to each case, such as nasal catarrh with thickening of the mucous membrane and a discharge. The glands around the neck were swollen, particularly those near the angle of the jaw. One or both nostrils would be found impervious, and some ozæna might be noticeable. There was generally more or less pharyngeal catarrh, with reddened mucous membrane, the hypertrophied tonsils showing a number of follicular cavities, interspersed with small white dots formed by the dried-up exudation of muco-pus. These symptoms were pretty constant in what he would term local chorea. He had seen many cases in which the head and shoulders would be thrown about in choreic spasms and in which the condition resulted directly from irritation of the nose or trigeminal nerve. Many of these cases were very unyielding except a correct diagnosis was made. Medicinal treatment did not avail, and no headway was made toward a cure unless the nasal irritation was removed. The convulsive processes usually began in the right hand, extended to the left, and then all over the body. He was in the habit of treating his cases mildly. The actual cautery might be used, but many patients got well if the parts were kept clean. A weak salt water wash with a small portion of alum, used every day, would do better than more vigorous treatment. In a number of cases he had begun by resection of the tonsils, and where hypertrophy existed a cure could not be effected unless this was done.

The Relation of Peripheral Irritation to Diseases of the Womb and its Appendages.—Dr. Charles C. Lee read a paper with this title. He said that in no part of the body was the relation of existing disease and peripheral irritation more frequent and complex than in the womb and its appendages, hence he had found the subject delegated to him no easy task. This condition naturally resulted from the greater sensitiveness of the nervous system of women than that of men, and the extreme potency of the uterus as a factor in the production of reflex irritation in other organs. The speaker called attention to a few of the well-marked neuroses, or, if the term was preferable, the hystero-neuroses, which he thought would best illustrate the subject. Omitting chorea, of which many cases were recorded as intimately dependent upon uterine and ovarian disease, the speaker said that the most frequent illustrations of peripheral irritation resulting from intrapelvic disease in women were (*a*) disturbances of surface temperature; (*b*) neuralgias, such as spinal irritation, spinal ache, sciatica, and migraine; (*c*) special forms of headache, such as pressure on the vertex while the rest of the head was unaffected; (*d*) neuroses of the gastro-intestinal canal, including the familiar example of the persistent vomiting of early pregnancy; (*e*) neurotic conditions of the breast, sometimes of the most aggravated character; (*f*) genito-reflex irritation of the respiratory tract, producing not only occasional dyspnœa, but unmistakable attacks of asthma; (*g*) hysterical affections of the joints and of the organs of special sense. The speaker did not attempt any minute subdivision or illustration of these general groups, but adverted to only two points of practical importance: First, it was futile to treat these evidences of peripheral irritation as diseases. Like all neuroses, they were symptomatic only of some more deeply seated disease elsewhere, and only by combining the appropriate local treatment of that with improvement of the patient's general health could we hope to achieve success. Secondly, it was a striking clinical fact that mal-conditions of the uterus exercised far more influence in these directions than disease of the tubes or ovaries. Undoubtedly we often found an oophoritis, or the evidence of cystic or sclerotic degeneration of the ovaries, in these cases. And in like association we also found the various forms of salpingitis. But however thoroughly these were treated, the neurotic complication would almost surely persist until the accompanying disease of the womb had disappeared. Whatever diseased condition of the uterus existed, this would have to be remedied before the patient could be cured. As had been previously stated, in neurotic conditions ablation of the uterine appendages was not only commonly useless, but often left the patient worse than she was before. That the appendages should be removed if intractable disease of their structure was unquestionable, to assume any other ground would be absurd. But, short of those conditions, they should be left where nature placed them, and, even when removed, in the treatment of such conditions as were now under consideration the accompanying uterine disease must receive the most anxious care.

The Relation of Peripheral Irritation to Disease, considered from a Therapeutic Standpoint. — Dr. Simon Baruch read a paper on this subject. He thought the most important element in the discussion of the above question was the influence of its decision upon our therapeutic procedures. Whether peripheral irritations were etiological factors by reason of sympathetic effect, as was formerly taught, or, as a more refined pathology and more scientific inquiry into pathological processes claimed to have been ascertained, it was due to reflex agencies, acting through the spinal cord, the chief aim of therapeutic endeavor must be at the point of irritation. He considered it just as important to adopt local treatment, whether the peripheral irritation produced symptoms through mechanical or reflex channels, but that it was always well to distinguish those conditions. The speaker related the history of a cure of true epilepsy, which verified the foregoing statement in regard to treatment: A. K., aged sixteen, a robust boy, had been suffering from distinct attacks of *grand mal* since the summer of 1884. The exhibition of bromides had resulted in the absence of attacks for over a year, but finally they returned with greater frequency despite the increased quantities of bromide administered. It had occurred to the speaker that an enchondroma on the left side of the anterior portion of the septum, which filled the entire fossa in front, projecting the ala far beyond its normal line, might be a peripheral irritant bearing ætiological relation to the epilepsy. After failure with the galvano-cautery, the growth was removed with a Bosworth saw. The bromides were continued until September, 1889, the patient not having had an attack since a week after the operation, which was in April of 1886. The bromides had been discontinued for the past seven months with no return of the attacks; this immunity for over four years could most probably be regarded as recovery from the disease. Similar cases were on record in recent literature. A disease like epilepsy, in the presence of which one stood almost helpless, demanded the most careful search for possible ætiological factors. If irritation of the probe in the nose produced the paroxysm of migraine, asthma, or neuralgia, we had evidence that could be obtained in no other organ, and, in addition, if we succeeded in removing attacks, either artificially or spontaneously produced, by complete cocaine anæsthesia of the sensitive areas, the ætiological connections were demonstrated beyond a doubt and the line of treatment clearly mapped out. It therefore became a duty to search for abnormal conditions in all those functional nervous disturbances which had been reported as possibly connected with nasal irritation. In other organs the difficulty of discovering points of irritation was not so marked, because interference with their function became more or less burdensome and called for remedy in a large proportion of cases. The eye, for instance, did not brook infringement upon its normal condition without protest—a protest which might or might not be heeded according to the intelligence of the patient and his capacity for resisting encroachments upon normal functions. The speaker himself had been cured of weekly attacks of migraine by having his error of refraction, unequal myopic astigmatism, corrected. If we did not succeed in relieving patients of the functional nervous diseases for which the ophthalmic examination was advised, we at least might be content that no damage had been inflicted by the correction of any error of refraction that might have caused distress from eye strain. From a therapeutic standpoint the eye, as a source of peripheral irritation, demanded as careful and painstaking investigation as did the nose. Fortunately, we had in these organs means of ascertaining positively the existence of points of peripheral irritation and of remedying them harmlessly. The existence of peripheral irritation in the utero-ovarian system had long been a vexed question. While the speaker was convinced that a lacerated cervix was frequently an ætiological factor of pronounced type, and while he advised removal of the local pathological conditions connected with the latter as a *sine qua non* to the improvement of the health of many suffering women, he was also convinced that these lesions rarely, if ever, gave rise to the functional nervous troubles that had been attributed to them. The latter might almost invariably be traced to conditions of general ill-health and anæmia, resulting from the local processes, which gave rise to muco-purulent discharges, to infection from raw surfaces on the cervix, and to interference by pain with comfortable locomotion, rather than to the pressure of cicatricial plugs. The speaker had searched the literature on the subject industriously for the clinical proof

that the removal of the nterine appendages had been instrumental in relieving prononnced fnnctional nervous diseases, and he was convinced that the ablation of diseased ovaries and tnbes did contribute to the improvement of health in a certain proportion of cases. But he could not bring himself to the belief that the removal of those organs not presenting palpable and well-defined pathological changes was ever called for. Serions psychoses might be traced to peripheral irritation resnlting from wonnds of the head, some of which had been cnred by excision of the scars. The relation of peripheral irritation existing in the gastro-intestinal tract to diseases elsewhere was well known. The speaker snmmed np his views on the therapentic relation of peripheral irritation to disease as follows: First, that the existence of peripheral irritation as an ætiological factor was well established. Secondly, that there need be no conjectnre in the search for such canses of fnnctional nervous diseases in many cases, because we had means in at least the more recently discovered sonrces, the eye and nose, of detecting and testing their existence. Thirdly, all harmless methods of treatment should be exhausted before mutilating procednres were adopted. Fonrthly, that whenever there was a donbt, the local condition should receive the benefit of that doubt, and treatment should be directed to the improvement of the general health.

Dr. Jacobi said that, while he had emphasized his belief that there conld exist cases of very intense chorea minor dne to nasal reflexes, it was of conrse important to be very careful in making the diagnosis. There was nothing easier than to be mistaken in serious cases. They were imbned with the notion that reflex irritation meant a great deal. He had his grave doubts as to the influence of peripheral irritation in producing any central disease. It had been customary with many of them —and they had been led, too, by illnstrions men—to believe that there was a great deal of sexual irritation in phimosis, and that to this condition might be traced many cases of paralysis in infants and older children. He had never seen such a case. He had given the subject generally nearly twenty-one years of attention, and he was now snre that he never shonld see such a case. They had heard of brain disease following or being prodnced by genital irritation. If a patient suffered from toothache or some severe peripheral nenralgia, snch symptoms might be really the local or reflex irritation marking the commencement of some central disease which, when it made its appearance, was often considered the canse of the nenralgic manifestations.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN PÆDIATRICS.

Meeting of April 10, 1890.

Dr. L. Emmett Holt in the Chair.

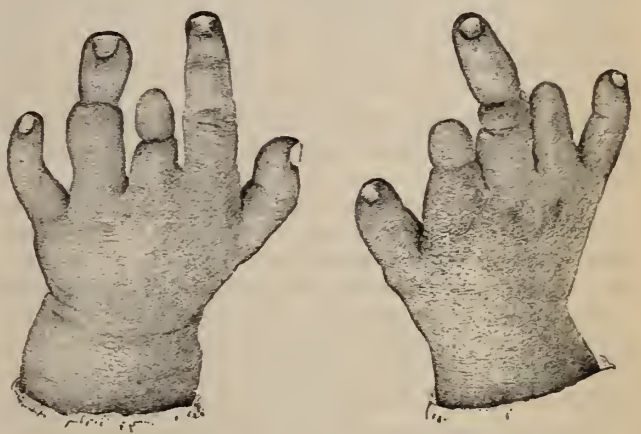
A Case of Cerebro-spinal Meningitis.—Dr. J. Lewis Smith presented an infant whose symptoms he described in detail and from which he had inferred that it had snffered from cerebro-spinal meningitis.

Dr. A. Jacobi thonght that the case had been one rather of some form of common meniugitis. He also thought that there existed considerable of the rhachitic element in the baby. There were some spots over the occipital bone which were still soft. There was a very perceptible pulse over the large fontanels which negatived the idea of existing inflammatory fluid. He should be disposed to place such a patient on antirrhachitic treatment, give more animal diet, and certainly give phosphorus, say $\frac{1}{150}$ grain three times a day. Under snch treatment he should expect to see a decided improvemeut in the child within fonr or six weeks.

Mulberry Stone in a Young Child; No Symptoms.—Dr. Hance presented a calculus which he had removed from a girl twenty months of age who had died from pulmonary tnberculosis and whooping-congh. During life the presence of the stone had not been indicated by any symptoms, and was only fonnd accidentally in making post-mortem section. It was a question whether the accretion was congenital. There were no signs of pyelitis.

Dr. A. Jacobi said the stone was of the mulberry variety and consisted of oxalate of lime. It was somewhat rare.

Congenital Malformation of the Fingers.—Dr. Walter L. Carr narrated the history and presented photographs of a case of congenital deformity of the fingers of both hands in a girl of two years of age. The mother had stated that the child was born with the membranes wrapped aronnd the hands, and that when cut away the fingers were fonnd to be marked. The deformed fingers were pecnliar in the numbers of annnlar constrictions. The index and third fingers of the left hand and the middle finger of the right hand showed this marking. On the right hand the index and third fingers were only the stnmps of the intra-nterine ampntations. The middle finger of the left hand was deformed in the same way and constricted near its extremity. The thnmbs and little fingers were not malformed.



The child was very active and ran around, taking hold of everything in the room. Her grasp was firm and the condition of her hands did not interfere with her play. Later in life the deformity might prevent her from doing snch work as sewing, though with training she might overcome the difficulty of holding the needle. If she used her left hand she might have no trouble at all, as the index finger was strong.

Empyema complicated with Pulmonary Œdema.—Dr. F. Huber read a paper with this title. (To be published.)

Impacted Urethral Calculus in a Boy of Three Years of Age.—A paper with this title was read by Dr. F. M. Crandall. (To be published.)

Two Fatal Cases of Acute Primary Pneumonia in Infants, without Fever.—The Chairman read a paper with this title. (To be published.)

Dr. A. Jacobi asked to what canse the chairman attributed the low temperatnre.

The Chairman replied: In the first case, to the intensity of the process, associated, as it was, with the gangrenous condition in the lnng. As to the cause in the second case, he had no explanations to offer. It had struck him as interesting to see two children die of pneumonia within a week of each other with none of the ordinary symptoms of the disease. Might not these cases have been of long standing? He had, during the past two weeks, seen several cases where babies had been brought in without very high temperatnre, and yet the antopsies had

shown quite extensive infiltration, in one instance involving the whole of both lower lobes.

Dr. Jacobi said there were three classes of pneumonia in which very high temperatures need not be expected: 1. That of old age. 2. The pneumonia of infants. 3. Pneumonia occurring in infants who had had other diseases by which they were reduced.

The Use of Spirits and Malted Drinks in Nursing Women.—Dr. Jacobi opened a discussion on this subject. He thought the question intimately connected with that of diet generally, as to whether it was possible for foreign substances in the blood to get into the secretions of the mammæ, and from there into the digestive organs of the baby. The speaker then dealt at length with the whole subject of the chemical and physiological experiments on milk secretion. He pointed out that the character and quality of the breast secretions of the mother were subject by many causes to continual variation. As long as the milk was a real secretion there was but little danger that any deleterious matter which might be floating in the blood would get admixed with the mammary secretion, but as soon as the woman became anæmic or got below par the secretion would no longer be simply milk, but part of it would be serum and other material foreign to its normal composition. Whatever floated in the serum would find its way into the mammæ and into the baby. This could be seen when we compared colostrum with milk. Conditions of the mother's milk, which in the later months of the child's nursing life would be absolutely devoid of danger, might, immediately after birth and while the milk still contained colostrum, produce much mischief.

Discussing then the subject of alcohol, the speaker said that the difficulty at once presented itself as to the woman's exact condition. Some women could take a certain quantity of spirits, while a feeble person taking the same quantity might produce results deleterious to the baby. It had been stated that the nursing woman must not have spirits, but that she must have beer. Most of those who insisted upon this point were the nurses themselves. Blood saturated with alcohol could not be good nutriment for the fœtus, and the same was true of the baby; and supposing the milk secreted to be, from any disturbance in the health of the mother, partly serum, then alcohol taken by her would certainly be found in the mother's milk. It might be true that this could only be urged in the case of those who were habitual drunkards, but he saw in the best families wet-nurses who would get drunk, and who would in that way be certainly likely to injure the baby. It had been stated, among other things, that alcohol increased the quantity of milk secreted. This had been also denied. There was only one remedy which, in the speaker's knowledge, would influence the secretion of milk and cause its increase, and that was salicylate of sodium. Alcohol, when taken, acted as the carbohydrates generally did. It had a certain amount of nutritive action, but when given in larger quantities it was not utilized in the milk production. This disposed, in the speaker's mind, of any idea of the necessity of giving malt liquors or spirits. There might, however, exist a necessity for its use on general medical principles. When stimulation was required, wine or beer might be indicated. The most that could be urged in favor of its general use was that a small quantity, if regularly given, would not be harmful. If it was expected that the hops in beer would act as a stomachic, it might be given with two or three of the meals. Whatever the carbohydrates in alcoholic drinks could do might be done equally well by carbohydrates administered in some other form. Whatever beer could do might be done just as well by milk and farinaceous foods, both supplying the large amount of albumin necessary. A woman who was not nursing, required ninety grammes of albumin daily, and one who nursed one hundred and sixty grammes. A greater amount of milk and farinaceous food in the woman's diet would supply this extra seventy or eighty grammes. He should prefer those foods which contained a large amount of albuminoids, such as oatmeal and barley.

Dr. E. L. Partridge said it seemed to him that benefit did arise, or at least an increase in the quantity of milk might be obtained, from the use of alcohol and malted liquors given in certain ways. Many nursing women were below par and were probably benefited. This fact might account in a great measure for their empirical use. High-pressure nursing by the use of stimulants was extremely undesirable, and would, he believed, determine functional disorders of the heart or pelvic organs, and bring about injury to the child. In cases where this high-pressure nursing had to be resorted to, it was better to make use of artificial feeding instead, for this, properly conducted, would be more beneficial at least to the child. As to any mischievous influences on the child from the moderate use of stimulants in the mother, he had been unable to trace such in his experience.

Dr. A. Seibert said that it seemed to him that in considering this question it was well to bear in mind not only the immediate effects of the alcohol on the mother and child, but also the bacteria which formed in some of the alcoholic beverages, especially beer, taken by the mother, and which he believed entered the milk and then the stomach of the infant, causing intestinal and other troubles.

Dr. E. H. Grandin said his personal experience would lead him to disagree with the remarks of the gentleman who had last spoken. He had never been able to trace any injury to the nurse or child from allowing the former a judicious quantity of malt liquors. As regarded the necessity for the use of alcohols, he should venture to dissent from the opinion of Dr. Jacobi. He had found that these anæmic women who possessed but little true glandular tissue in the mammæ, and made such poor nurses, could be made to give good milk in fair quantity by the judicious administration of malted liquors in the form of ale, porter, or stout. The women who possessed good breasts and plenty of milk and who could be taught to nurse their babies at regular intervals, he had not found in need of malt or alcohol. Those who were too feeble to nurse without stimulants he allowed to have it, and with direct benefit rather than injury to the child, their use not only increasing the quantity but the quality of the milk given. He had never seen a single instance where he could trace any gastro-intestinal disturbance to the use, in moderation, of malt liquors.

Dr. Jacobi said it appeared to him that the opinions of all the gentlemen who had spoken were about the same. They all agreed that liquors were unnecessary and mostly injurious, or that they ought to be used, if at all, for stomachic or tonic purposes. If medical men in general practice were guided by such opinions, they would be pretty sure to do what was right for the woman.

Reports on the Progress of Medicine.

PHYSIOLOGY.

By LOUISE G. RABINOVITCH, M. D.,
PHILADELPHIA.

The Fate of Sugars and their Effect on the Organism.—M. Albertoni (*Jour. de méd., chir. et pharm.*, No. 7, 1889) considers the question of the absorption of sugars which are ingested in considerable quantities

as food to be important; it concerns, he thinks, both physiology and pathology, as far as it relates to the pathogenesis of diabetes.

With reference to the absorption of glucose, the works of Funke, von Becker, Smith, Meade, Aurep, and Tappeiner are mentioned, with the objection, however, that the animals experimented upon by these authors were under special or artificial conditions, and that in general their works show only that glucose is absorbed in the gastro-intestinal tract, without specifying the quantity and limits of absorption, especially in the normal state of the system.

On the ground of his experiments, M. Albertoni thinks it is incorrect to admit that the absorption is regulated by the physical laws of density of liquids. The object of his work is to determine the rapidity and intensity of absorption of glucose solutions of different degrees of concentration introduced into the gastro-intestinal tract under normal conditions.

The author experimented on dogs which were deprived of food for twenty-four hours. The amount of sugar in the solution ingested or injected, and the time that it remained in the gastro-intestinal tract, having been known, he was enabled to judge of the amount of sugars absorbed for a given time by collecting the remaining liquids in the same tract after sacrificing the animal and testing the liquid, previously purified, by means of different chemical methods.

An elaborate table of experiments is given, and the author concludes that the rapidity and intensity of the absorption of glucose are considerably greater than they have been supposed to be. According to the table, the absorption of glucose in an hour amounts to from sixty to sixty-five grammes, and during the subsequent hours the quantity absorbed diminishes; the explanation of this is, as alleged, that, the organism being saturated with glucose to a given point, its absorbing property for the glucose diminishes.

The statement as regards absorption is true of glucose solutions of less as well as of greater density than that of the blood, the fact being more conspicuous, however, in the former case. The sugar solution remaining in the stomach unabsorbed diminishes always in density, which may become inferior to that of the blood, but is superior to that of the plasma.

The glucose disappears from the stomach independently of the quantity of water in which it is dissolved, and disappears in greater quantity than the water that holds it in solution, without respect to whether the solution is of less or greater density than the water.

It is probable, Professor Albertoni thinks, that the absorption is accomplished in the stomach itself; it always contains the unabsorbed mass of liquid. He seeks confirmation of the statement in one of the experiments in which the vagi were cut through; because of the induced pyloric insufficiency, the intestine contained much more liquid and glucose than in any other experiment.

The effect of sugars on the circulation is under consideration in the second part of the work, and this is stated to be the first work on the subject.

A. Action on the Blood-pressure.—The author published his first work concerning the question some years ago, in which he endeavored to show that saccharose and glucose injected into the blood in moderate doses augmented the blood-pressure, and that this was manifested instantly, lasting as long as the blood contained an excess of sugar. The degree of augmentation of blood-pressure is not in relation with the quantity injected, but its duration is, for the organism needs a longer time to eliminate the excess of sugar.

It is known now, the author alleges, that maltose is formed at the same time with the glucose, and, having used pure maltose in his experiments, he found this substance to act like glucose and saccharose.

The results of the experiments are given in a table which shows the decided augmentation of blood-pressure, the mechanism of which is explained as follows:

1. The augmentation of blood-pressure is brought about neither by the influence of the vaso-motor centers nor by the action on the capillaries themselves; the vessels dilate relatively after injection of glucose, and the blood-pressure augments whether a section is made of the cord beneath the calamus or of the cord and the vagi.

2. The augmentation of pressure is not dependent upon paralysis of the vagi, since it remains the same after section of these nerves, and, in case of the pressure being augmented by glucose injections, the pressure increases progressively after the section of the nerves.

The heart is the organ that shares in this augmentation of blood-pressure; the increased frequency of the heart-beats is not the essential factor necessary to accomplish this, for in dogs whose vagi are cut the pressure increases after injection of glucose without the pulse becoming more frequent. It is the increased systolic excursion that maintains the elevation of pressure. This fact was evident from experiments on frogs whose heart-beats were obtained by Marey's apparatus. A few drops of a one-per-cent. glucose solution were poured on the cardiac muscle, and the elevation of blood-pressure was most conspicuous. The reasoning does not hold good if the increased pressure is explained by the presence of an additional amount of liquid in the shape of the solution in the blood; for, firstly, the added mass, from four to eight grammes, which suffices to augment considerably the pressure, is too small to be looked upon as a cause of augmentation; secondly, the coexisting vascular dilatation would compensate sufficiently for the additional liquid mass.

The supposition that the phenomenon might be due to the fever induced by the injection into the blood is to be excluded with certainty, for the effects are instantaneous and last as long as there is an excess of sugar in the blood.

B. The Action on the Frequency of the Pulse—This augments with the blood-pressure, the ratio being 20 to 40 pulsations a minute, according to what animal is used after an injection of from 15 to 30 grammes of glucose, maltose, or saccharose. It lasts until the excess of sugar is eliminated from the blood. This augmentation in the frequency of the pulse is not met with in either rabbits or dogs whose cervical vagi are cut.

The author experimented on human subjects, administering sugar by the mouth; he concludes that a slight augmentation in the frequency of the pulse is noticed, which is manifested more or less quickly according to different accidental and secondary circumstances. In cases where there was nausea the pulse failed to become more frequent.

The foods, the author concludes, containing starches and sugar have certainly an analogous action on the organism, and this explains certain physiological phenomena subsequent to meals.

C. Action on the Blood-vessels and the Velocity of the Circulation.—The action of glucose on the vessels is determined by observing the change in volume of the organs, and the quantity of blood flowing out from an opened vessel in a unit of time.

That sugar dilates the blood-vessels was inferred from the augmentation of the limbs in volume; this was verified by means of Roy's apparatus, and the quantity of blood shed from a given vessel in a unit of time was double the normal. The rapidity of the circulation was decidedly increased.

D. The Influence of Sugars on the Urinary Secretion.—A number of authors, it is said, are of the opinion that in diabetes the extraordinary increase of the amount of urine is dependent upon the elimination of sugar; special researches on the subject have been made only recently by Richet, Moutard-Martin, and the author himself. According to Richet and Moutard-Martin, a small amount of sugar in the blood—0·50 gramme to the animal's kilogramme of weight—is sufficient to induce a noticeable polyuria. It is not to be attributed to the water absorbed with the solution, for ten times the volume of pure water injected will not produce the same effect.

The author professes to have investigated the question before the authors named (*Giornal. di quest. acc.*, v. v, xxix, p. 178), and to have endeavored to point out that the duration and intensity of the induced polyuria varied according to the quantity of sugar injected. The polyuria and glycosuria are not dependent upon spinal irritation, which might give similar results; the same phenomena are observed in dogs with the spinal cord divided below the calamus.

Neither is the fact to be attributed to the increased blood-pressure, for the same is the case in rabbits, which present no modification of blood-pressure.

The dilatation of the renal vessels and the increased rapidity of the circulation determined by the glucose are said to account partly for the polyuria. Besides the indications of these facts by the angeiometer, there is some special effect of the sugar on the uriniferous tubules.

Munk is quoted as having shown on an isolated kidney that the addition of a half per cent. of sugar to the blood led to the production of eight times the normal amount of urine.

Maltose is assimilated in the same proportion as glucose; this is in accordance with the results of Dastre and Bourquelot.

Morphine and chloral interfere with the effects of sugar on the circulation, and have but little influence on the polyuria and glycosuria. Since these drugs are used in diabetes, their effect was tested by administering them before injecting the sugar in small doses. They seemed to check the polyuria and glycosuria to some degree, but this was not the case when large doses of sugar were given.

The experiments show that sugars are not only foods, but at the same time agents modifying the functional actions of the organism. Sugars entering the blood after meals affect the circulation in a way opposite to the enfeebling action of some albuminoid derivatives of peptones that can be formed in the process of digestion (the peptin of Albertoni, the peptonin of Brieger).

Cohnheim is quoted as saying that the accumulation of sugar in the blood is the center of all the phenomena of diabetes, and it is presumed that the same phenomena may be induced artificially by injecting sugar into the blood. The quantitative modifications of the urinary secretion and the changes in the circulatory apparatus are equally produced and are transitory in diabetic patients.

It remains to decide, the author remarks, what the reasons are for the accumulation of glucose in the blood of diabetic patients.

Some Results of Sphygmometric Experiments.—After the description of his sphygmometer and the conveniences of its use, M. A.-M. Bloch (*Comptes rendus de la soc. de biol.*, No. 26, 1889) mentions the precautions necessary for obtaining accurate results, and represents, in figures that are of relative more than of absolute value, the following results of the experiments on his own person relating to the influence of ingested food on the arterial tension:

		Arterial tension.
7.00 P. M.	(immediately before dinner)	575 grammes.
7.30 "	(immediately after dinner)	575 "
7.45 "		675 "
8.00 "		750 "
8.20 "		725 "
8.45 "		650 "
9.00 "		700 "
9.15 "		650 "
9.30 "		625 "
10.30 "		575 "

The increase of arterial tension after meals is especially noticeable if coffee is taken at that time.

The table shows a rapid augmentation of arterial pressure during the hour following meals; then there is gradual fall to the initial standard after the lapse of about three hours. The 700-gramme pressure found at nine o'clock is thought to depend upon some respiratory or other accident, investigation of which has not been made.

In the following table the author represents more striking results:

11.45 A. M.		550 grammes.
1.00 P. M.	(immediately after meals, coffee included)	625 "
1.30 "		650 "
1.45 "		800 "
2.15 "		775 "
3.00 "		550 "

This shows augmentation of arterial tension beginning after meals, continuing the hour following, and attaining 800 grammes, to reach to the initial figure 550 at 3 P. M. Moderate gymnastic exercise is stated to lower arterial pressure, and after the augmentation the initial standard of arterial pressure is reached at a shorter period if exercise is taken after meals.

It is further suggested that the least irregularity in the respiration is very apt to modify the results profoundly, though this is only for a short time. The author confirms the statement by having obtained an arterial pressure of 625 grammes at the time of violent effort, and that of 800 grammes immediately after the exertion.

In conclusion, the statement is made that, for the purpose of obtaining correct pressure-records in the sick, it is necessary to take strictly into consideration the hour of the day, the ingestion of food, and the physical exertion that preceded the sphygmometrical operation. The respiration is to be inspected carefully during the experiment; of much importance is the attitude of the patient; it must be absolutely the same whether the results are to be compared with those found in the normal person or in the patient himself.

Electrical Discharges of the Human Skin under the Influence of Different Forms of Psychical Activity and of Excitation of the End Organs.—Professor Jean, of Tarchanoff (*ibid.*) describes the method of observation in his experiments by means of either Meissner's or Wiedemann's galvanometer. After mentioning the necessity of securing perfect tranquillity of the subject and quiescence in the operating-room, he summarizes the results under the following sections:

1. *Excitation of the Sense Organs.*—Any slight irritation is apt, after a latent period of from one to three seconds, to bring about a cutaneous current that develops and increases gradually; its existence is indicated by the deviation of the galvanometric needle. The direction of the current indicates that the cutaneous regions, rich in sudoriparous glands—such as the palm of the hand and the sole of the foot—become, during the period of excitation, negative in comparison with parts poor in the same glands. In the hand, as well as in the foot, an ascending cutaneous current is developed; it persists for a considerable period, several minutes after which time it declines by a gradually diminishing curve of oscillations. Frequent repetition of the excitation leads to final non-respousiveness. The same results are obtained when the agent of excitation is electricity, thermic or painful impressions, the sound of an electric bell, the visual impression of light, or odorous substances acting on the corresponding organ of perception. Under the various conditions the difference of the manifestation of the cutaneous electric current is quantitative and not qualitative. The manifestation of the current, the author thinks, depends upon the activity of the sudoriparous glands, for the reason that the current is insignificant in regions where these glands are scarce.

2. *Psychical Representation of Different Sensations and Emotions.*—Imagination of any irritation, warmth, pain, joy, etc., is sufficient to make the applied galvanometer indicate development of an electrical cutaneous current that often even surpasses in intensity that obtained by immediate and real excitation. The kind of imaginary excitation has something to do with the intensity of the current, thus: The current is of greater intensity when a feeling of warmth than when that of cold is imagined.

3. *Intellectual Work.*—The intensity of the cutaneous current caused by mental work is in proportion to the difficulty with which the same is performed. The marked influence of mental work on the manifestation of the cutaneous current is evident from the fact that, in cases of subjective exhaustion, or overexcitation, when artificial irritation remains fruitless in causing the current, the latter appears readily in case the person in question is made to perform hard mental work, such as solving a difficult arithmetical problem.

A person in a condition of expectant attention, it is remarked, is unsuitable for experimentation, since this condition causes the galvanometric needle to be in constant oscillation.

4. *Voluntary Muscular Innervation.*—Each muscular contraction is followed by a cutaneous current over the entire body. That not the muscular contraction itself, but the voluntary psychical effort used for the accomplishment of the latter, is the immediate cause of the current the author proves by the fact that a voluntary movement of a toe is sufficient to excite a cutaneous current in the hand, which continues even after the toe is perfectly immobilized, and the intensity of this current is in proportion to the degree of the voluntary effort used.

The conclusion follows that all nervous and psychical efforts in man are accompanied by electrical cutaneous phenomena, or discharges, that represent the physical manifestation of the cutaneous glandular activity always going on during nervous or psychical function. According to the author, the glandular system plays the rôle of a thermic and chemical regulator. In fact, he says, each nervous or psychical act is the source of an increase of heat and of products of disintegration, carbon dioxide being one of those that must be eliminated. The sudoriparous cutaneous glands participating in all nervous and psychical

functions diminish, at the same time, the body temperature, augment evaporation, and in this way free the body from the different products of disintegration, the accumulation of which would do harm to the organism.

It is to be admitted that there is an intimate anatomical correlation between the nervous centers of sensorial, psychical, and voluntary motor activity and the nervous centers of the cutaneous and other glands; and that the cutaneous glandular apparatus is the safety-valve against exaggerated body heat and harmful products of accumulation that result from nervous and psychical activity.

The Precritical Discharges in Acute Diseases.—M. Albert Robin (*idem*, No. 15, 1889) professes to have demonstrated the following before the appearance of MM. Roger and Gaume's work relating to the same question:

In typhoid fever the organism is the seat of retention of toxic products; the degree of retention is in proportion to the gravity of the disease; the defervescence, and even the convalescence, is subordinate, in the majority of cases, to the true discharge of the toxic products.

The reality of the retention has been proved by the following facts:

1. Extractive matter in the blood is in direct proportion to the gravity of the disease. In benign forms of disease the quantity of the extractive ingredients in the blood is always higher than under normal conditions.

2. Diminution of the urinary extractives coincides with augmentation of the blood extractives, and at the same time with aggravation of he disease.

The subordination of the critical phenomena to the urinary discharges the author demonstrates as follows:

1. The urinary eliminations follow an ascending course, beginning with the attack; if 50 grammes, on an average, are excreted during the period of the attack, there are 56·50 grammes during the period of defervescence, and 60·13 grammes during the period of convalescence.

2. All phenomena of a critical character are accompanied by an excess of eliminated urinary solids. To decide whether the eliminated sweat during an attack is indifferent or critical, it suffices to find out whether there is diminution or augmentation of the quantity of urine and its solids; diminution shows that it is indifferent, and a gmentation that it is critical sweat.

3. The first thermic signs of defervescence are preceded, in 75 out of 100 cases, by an augmented elimination of urinary solids; this takes place twenty-four hours before defervescence. In 23 out of 100 cases this augmented elimination continued during the first day of defervescence. In 24 out of 100 cases it preceded the period of defervescence for from forty-eight to seventy-two hours. It was absent in eighteen per cent. only, of which six per cent. belonged to cases of benign relapses during the course of a benign attack; eight per cent. belonged to very mild forms, and four per cent. to intermediate types. If, instead of taking a hundred typhoid cases in general, the same number of grave cases is considered, the author says he has demonstrated that the discharges he calls *précritique* are observed to be constant. Aside from the importance of these discharges from the physio-pathological standpoint of the crisis, their precritical existence may be a clinical guide in the prognosis, for often the classical signs of defervescence are preceded by it several days in advance.

4. A more or less sudden abortion of a grave attack of typhoid fever is the consequence of a brisk elimination of the *débris* of organic disintegration.

5. The period of convalescence includes, too, a precritical discharge, for in seventy-five per cent. of typhoid cases the quantity of eliminated disintegrated matter was augmented about twenty-four hours before the time when the evening and morning temperature did not go higher thau 38° C.

6. The elimination of creatin does not reach its maximum until the third or fourth week of the disease. The maximum is often found at the time of the subsidence of the grave symptoms.

7. Elimination is performed by the kidneys, which are assisted by the same process in other organs.

8. In ordinary forms of typhoid fever the waste elimination is a progressively ascending one in the various successive periods; this is not the case in fever with relapses, which leads one to infer that the relapse occurs because of the imperfect waste excretion during the first subsidence.

9. The critical influence of certain intestinal hæmorrhages and that of epistaxis seem to be destined to excrete poisonous matter from the circulatory system briskly.

The author's experiments related to typhoid fever and other acute diseases, in all of which the waste excretion was found to be reduced.

In conclusion, the author says that the so-called typhoid state, being of much importance in the prognosis of the disease, is caused by retarded excretion of waste matter; this is due either to an excessive production or to an absolute or relative insufficiency of excretion. It is an external expression of the self-intoxication from what he formulates as augmented disintegration, diminished oxidation with retention of waste products.

The importance that he ascribes to his researches is that they enable one to institute a mathematically rational treatment in the different periods of the acute diseases. To the author himself this guide has proved of good service at the bedside. The results were communicated to the Biological Society in 1886.

Miscellany.

The American Society of Microscopists will hold its next meeting in Detroit, on the 12th, 13th, 14th, and 15th of August.

The general session for the reading of papers will be held in the new building of the Detroit College of Medicine, corner of St. Antoine and Catherine Streets and Gratiot Avenue.

The Mayor of Detroit will deliver the address of welcome, to be followed by the response of the president of the society. The Tuesday afternoon session will be devoted to the reading of papers aud society business. In the evening a conversazione will be held at hotel headquarters. On Wednesday evening the president will read his annual address, on The Influence of Electricity on Protoplasm. The Thursday afternoon session will be devoted to the various technological features of microscopy, such as the preparing, staining, and mounting of specimens, section-cutting, manipulative methods, etc. In the evening there will be an exhibition of microscopes and objects, popular in character.

The programme iucludes the following titles: Micrometry, by Professor William A. Rogers, of Waterville, Me.; Uniformity in Tube Length, by Professor Simon H. Gage, of Ithaca, N. Y.; Fees of Experts with the Microscope, by C. M. Vorce, Esq., of Cleveland, Ohio; The Full Utilization of the Capacity of the Microscope, and Means of obtaining the Same, by Edward Bausch, Esq., of Rochester, N. Y.; The Structure of Protoplasm, and Microscope Objectives, by Professor T. J. Burrill, of Champaign, Ill.; Abnormal Forms in the Diatoms, and Conclusions therefrom, and Review of Some of the Generic and Specific Distinctions in the Family *Coscinodisceæ*, by the Hon. Jacob D. Cox, of Cincinnati; The Microscopic Identification of Hair, The Effect of Curvature of the Cover Glass upon Micrometry, Description of Scale (5), manufactured by Marshall D. Ewell, in pursuance of Resolution of A. S. M., adopted in 1889, A New Form of Stage Micrometer, Some Experiments to Determine the Limit of Vision as Related to the Size of the Object observed, and A Review of Some of the Medico-legal Questions involved in the Cronin Case, by Professor Marshall D. Ewell, of Chicago; Observations on the Blood in Health and Disease, by Dr. Simon Flexner, of Louisville; The Transition from Columnar to Stratified Epithelium, and Picric and Chromic Acid for the Rapid Preparation of Tissues for Classes in Histology, by Professor Gage; The *Rotifera* of Central Michigan, and Recent Methods of investigating Microscopical Animals, by Professor D. S. Kellicott, of Columbus, Ohio; Some Methods of treating Nerve Tissue, by Dr. William C. Krauss, of Buffalo; An Infallible Method of preparing Injecting Gelatin and injecting Small Animals, and Observations on Mounting, by Dr. R. N. Reynolds, of Detroit; Résumé of the Past Year's Advance in Microscopy, by Dr. Lee H. Smith, of Buffalo; and A New Flash Light in Photography as applied to Microscopy, Postal Cards and Vegetable Fibers, The Possibilities of

the James Cement, with Many Fine Specimens, by Dr. Thomas Taylor, of Washington.

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for June 27th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—									
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.
New York, N. Y.	June 21.	1,617,000	773	..	..	..	..	..	..	3	11	29	10	8
Chicago, Ill.	June 21.	1,100,000	292	..	..	..	..	..	..	27	4	7	2	1

Foreign and American Brandy.—In the course of an editorial reply to an inquiring correspondent, *The Sanitarian* for June says:

"Pure brandy has the distinctive odor of the essential oil of grapes, *huile de Cognac*. But the misfortune is that this oil is largely used to counterfeit brandy by giving odor to other distillations. Moreover, in France especially, brandy is frequently distilled from poor wine or the juice of bad grapes, such as have failed in maturing or become acid and unfit for wine—or anything else. It seems almost needless to remark that all such brandy is of poor quality—no matter how exquisitely it may be flavored—but it is abundant. *Time* is an essential element in the production of good wine and brandy alike—time after fermentation and distillation required for the combination of the contained ethers and essential oils produced by fermentation and distillation. But, besides, there is an acquired art in regulating the distillation of brandy, the flavor being influenced by the greater or less rapidity of conducting the process. When this is lacking, as it too often is under inexperienced manufacturers, the product is of inferior quality and subjected to such additional treatment as may improve the flavor but aggravate the quality. English brandy is usually prolific in *fusel oil*. The foregoing remarks apply more or less to all imported wines and liquors; substitution and adulteration are common practices, and the difficulty in obtaining those that are pure is greater than it is among American manufacturers. Indeed, it has long since been demonstrated that almost everywhere south of the fortieth degree of latitude in the United States the soil and climate are well adapted to the cultivation of the vine; and forty years' experience in California particularly, since Longworth so successfully exhibited the results of even a less favored region, there has been no lack of ambitious manufacturers, until some of our domestic wines and brandies will favorably compare with even the choicest importations. True it is, as above implied, that the different conditions of climate—not always appreciable—season, and soil, the different modes of culture of the vine, the different management in the processes of fermentation and distillation, and the different means of preserving both fermented and distilled liquors—all contribute to the results. But the Californians have not been slow in the acquisition of all such knowledge, and it is now concentrated to such a degree that they can well afford to challenge comparison. Judged by samples, of which we have availed ourselves of the opportunity to examine, the wines and stronger liquors sold by the California Vintage Company, New York, will compare favorably with the same varieties from any other source."

ANSWERS TO CORRESPONDENTS.

No. 323.—We do not understand that the requirements of the act apply to physicians already in practice in the State.

No. 324.—The action of the two drugs is not antagonistic.

No. 325.—Two specimens of the urine are examined at the same time. Yeast is added to one of them, and the bottle is corked loosely and kept in a warm place for twenty-four hours. The other one is kept at the same temperature, but without the addition of yeast. Then the specific gravity of each of the specimens is taken, when it will be found that the fermented specimen has lost in density, and each degree of density lost represents the original presence of a grain of glucose in each fluidounce of the urine. For example, if the specific gravity of the unfermented specimen is 1·030, and that of the fermented specimen 1·020, the urine contained ten grains of glucose in each fluidounce.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

ACCIDENTAL SUFFOCATION AS A CAUSE OF SUDDEN DEATH.*

BY HERMANN M. BIGGS, M.D., AND WILLIAM T. JENKINS, M.D.,
CORONER'S PHYSICIAN.

THE subject of sudden death and its causes does not often receive from physicians much consideration, largely, perhaps, because they are accustomed to consider that their responsibility has reached an end when death has occurred, or at least in these cases the responsibility is then delegated to the proper officials.

Something more than a year ago one of us published a paper directing especial attention to one of the most frequent causes of sudden death, and one which has received but insufficient recognition—viz., the rupture of aortic aneurysms. In that paper attention was called to the infrequency of the determination of the cause of sudden death by physicians other than the coroners' physicians. In cases of sudden death among the poorer classes the physician who may be called does not interest himself sufficiently in the case to request an autopsy, and among the better classes, even if the physician desires an examination, the friends usually object to its being made. The prevailing opinion among physicians is that the cause of sudden death in a large proportion of instances is some form of heart disease (especially disease of the myocardium) or cerebral hæmorrhage, and to one of these causes death in such cases is usually ascribed.

We desire in this paper to direct attention to the frequency of accidental suffocation as a cause of sudden death and to report a series of cases, some of which have considerable interest because of their uniqueness.

In children it appears to us that no other cause compares with this in frequency in the production of sudden death, and among adults it is far more common than is generally supposed. Excepting in those cases of accidental suffocation where death results from the lodgment of foreign bodies in the air-passages, the cause of death must often be determined by the detailed history, obtained only after careful questioning of the friends, by the external appearances of the body, by the general evidences of death from suffocation, found in the internal organs, and by the absence of any other determining cause for death.

In many cases the history, if carefully drawn out, will show that the subject was an epileptic or an alcoholic and was found lying on the face dead. If the subject is an infant, the history will probably show that the position in which the child was found was such that there was obstruction in some way of the openings of the mouth and nares. It is very painful to the mother and often quite unnecessary to bring out this fact too clearly.

The external appearances are often of great value in determining the cause of death. In death from suffocation the blood usually remains fluid, and suggillation is very much marked. The position of the livor mortis on the anterior, posterior, or lateral surfaces of the body often gives the key at once to the posture of the body at the time of death, and its absence at certain points on these surfaces indicates the points of pressure here, and sometimes from the stamp thus produced on the soft parts the character of the object producing the pressure may be determined. Internally the blood is found to be fluid, the heart is in diastole, the lungs and bronchial mucous membrane are deeply congested, there are, perhaps, petechial hæmorrhages in the pleura and the pericardium, and there is a general congestion of the abdominal organs. The history in such cases, with the external and internal appearances just detailed, point in the most unmistakable manner to death from suffocation.

The illustrative cases reported in this paper, as well as all those upon which it is based, occurred in the services of the coroners' physicians, and, with one or two exceptions, all occurred in the service of Dr. Jenkins.

Cases of accidental suffocation, for convenience, may be grouped under the following heads:

1. Accidental suffocation produced by the lodgment of foreign bodies in the larynx or trachea.
2. Cases of accidental suffocation of infants by obstruction of the mouth and nares.
3. Accidental suffocation in epileptics during convulsions and in alcoholic subjects during intoxication.
4. Various other causes producing closure of the air-passages, including submersion, inhumation, strangulation, etc.

This fourth class of cases will not be considered in this paper.

The cases grouped under the first head, the lodgment of foreign bodies in the larynx or trachea, may be divided, for convenience, into those occurring in children and those occurring in adults; the former are by far the most common. In them the foreign body in a large proportion of cases is some object that the child has found and put into its mouth (in accordance with the habit so common in children), and which has been drawn into the larynx during some sudden inspiratory effort. The object may also be some article of food. In adults the foreign body is almost invariably an alimentary bolus, and usually meat. The rapidity with which death occurs in these cases depends upon the completeness of the obstruction of the air-passages and the violence of the reflex symptoms. If the obstruction is not complete, it is often made complete by spasm of the glottis. In such cases death apparently often occurs within five minutes; it is rarely more than ten, and not infrequently it is instantaneous.

One or two of the cases reported in this paper illustrate the occurrence of instant death by lodgment of a foreign body in the larynx, and the following case, published by Perrin,* also shows the manner of death: An old man, aged sixty-eight years, fell suddenly as if struck by lightning while leaving a café. At the autopsy an alimentary bolus composed of pancake was found, filling the post-pharyngeal cavity and extending forward to the orifice of

* Read before the New York Clinical Society, January 24, 1890.

* Reported in Poulet's *Foreign Bodies in Surgery.*

the glottis; the epiglottis was raised. Numerous cases similar to this have been reported. In them there are frequently no signs or symptoms of obstruction of the air-passages during life, and in fact death is so nearly instantaneous that there is no time for the manifestation of signs or symptoms of any kind. In these cases the post-mortem appearances do not suggest that asphyxiation was the cause of death, and the nature of the cause will almost certainly escape recognition at the autopsy unless the possibility of accidental suffocation is kept in mind and the larynx is removed and examined. (As a rule in this country, unless there is something to direct attention to the larynx, it is not removed or examined in autopsies.)

In those cases where death is instantaneous, or almost instantaneous, it apparently is the result of reflex inhibition of the heart's action through the fibers of the pneumogastric nerve. Certainly it is not produced by asphyxiation.

Not only may death be produced by the entrance of solid foreign bodies, but numerous cases have been recorded where it has resulted from the entrance into the larynx or trachea of fluids. In such cases death results either from the filling up of the bronchi and trachea with fluid or from the intensity of the reflex phenomena and the spasm of the glottis. In fact, in all cases of foreign bodies in the larynx these latter symptoms are the most alarming ones.

Guyon* reports a case where instant death resulted from the cauterization of the larynx by dilute ammonia. Death was apparently caused by spasmodic contraction of the glottis.

A case is reported from the Italian by Poulet,† in which a child was found chewing some coal. The mother surprised him and made him drink some water hurriedly. Part of the fluid fell into the trachea and rapidly produced death.

The opening of large abscesses or tubercular cavities into the bronchi or trachea may sometimes produce death in the same manner as in the introduction of fluids from without; numerous such cases are on record. Reasoning *a priori*, it would seem as if a simple spasm of the glottis could not result in death, because the spasm would be relieved before complete asphyxiation had occurred. The fact, however, seems to be that, although this is perhaps in part true, yet sometimes, when the spasm is relieved, the respiratory centers have become so benumbed from the action of carbonic-acid gas, or the want of oxygen, that no further efforts at respiration are made. The motor center of the larynx is probably far more tolerant of carbonic-acid gas or want of oxygen than the respiratory center, and motor impulses may continue to be sent out from this, producing spasm of the glottis, even after the irritability of the respiratory center had been completely lost. Benumbing of the respiratory center would seem to be the cause of death in those cases where death occurs during the operation of tracheotomy, when respiration ceases and the action of the heart continues, but respiration can not be re established even after the air-passages are opened and the obstruction is removed.

In almost all the cases where foreign bodies are drawn into the larynx the immediate cause of the obstruction is some sudden inspiration—in laughing, coughing, shouting, or something causing surprise or fright, or some sudden start.

Cases of Sudden Death from the Lodgment of Foreign Bodies in the Larynx or Trachea.

Case I.—A boy, aged fifteen years, was playing in one of the city parks during recess for dinner; suddenly he fell to the ground, became deeply cyanosed, and grasped his throat. His companions thought he was having a convulsion. A physician was sent for, but before his arrival the boy was dead. Death occurred, probably, within five minutes. He was removed to his home, and death was ascribed to heart disease. At the autopsy a collar-button was found in the larynx, with the head below the vocal cords and the base of the button resting upon the cords. The opening in the glottis was completely closed. Aside from this, the organs showed the lesions usually found in death from suffocation.

Case II.—A school-boy, aged ten years, acting as monitor of his class, was suddenly seized with difficulty of breathing, became quickly unconscious, and died. The teacher, who was a physician, thought the boy had had an epileptic convulsion. The boy had been eating some bread and butter. At the autopsy his face was still deeply cyanosed, and there was found in the larynx a mass of soft, fatty matter that melted at the temperature of the human body. The usual lesions in death from asphyxiation were found in the other organs.

Case III.—A child, aged about five years, while playing about his father's knee on the sidewalk and eating an orange, suddenly became cyanosed, the respiration became difficult, and he fell to the sidewalk. The father, supposing he was having a convulsion, took him into a drug-store and gave him a hot bath. In about five minutes the child was dead. Several physicians were present, who expressed the opinion that the child died from heart disease. At the autopsy the face was still deeply cyanosed. The usual lesions in death from asphyxiation were found; in addition, the bronchial glands were greatly enlarged and the left primary bronchus was somewhat compressed. Just above the bifurcation of the trachea there was an opening, through which a bronchial gland had been discharged into the trachea and had lodged just at the bifurcation of the trachea in the opening of the left primary bronchus. The gland was enlarged and the center cheesy. Around the cheesy center a suppurative inflammation had occurred, which, extending through, had produced ulceration in the wall of the trachea, and thus the loosened cheesy mass had made its way into the trachea. A case quite similar to this was reported in the *Deutsche medicinische Wochenschrift* of 1887, which occurred in a hospital while the physician was in the ward. A diagnosis of obstruction in the air-passages was made, tracheotomy was immediately performed, the cheesy gland removed, and recovery took place.

Case IV.—A child, aged three years, left his bed in the morning and was eating a piece of cake; on returning to his bed he suddenly showed great difficulty in respiration. The mother thought the child had drawn a piece of cake into the larynx, and introducing her finger into the throat, felt the head of what was apparently a screw. She sent for a friend and they endeavored to dislodge the screw, but in doing so held the head backward with the face turned up. A physician was sent for, but before his arrival the child was dead. At the autopsy a screw was found lodged in the larynx, with the head resting upon the vocal cords and the shaft extending down into the trachea.

Case V.—A boy, aged about five years, while playing with

* *Dict. encyclop.*, art. Larynx.

† *Foreign Bodies in Surgery.*

a small rubber balloon with a whistle attachment, suddenly drew the balloon and whistle into his throat. It was so lodged that with each expiration the balloon was partially inflated; before it could be removed the boy was dead.

Case VI.—A girl, aged about ten years, was holding a jack in her mouth, when a sudden inspiration drew it into the larynx, where it became firmly fixed, and before it could be removed death had occurred.

Case VII.—A man, aged about forty-five, who had been indulging freely in liquor, after ordering and partaking of part of a steak in a restaurant, suddenly fell from his chair to the floor and died; death was almost instantaneous, and was supposed to be due to heart disease. The history led to the suspicion that death had been produced by the lodgment of a foreign body in the larynx, and, on opening the trachea, a large piece of meat was found lodged firmly in the larynx between the vocal cords.

Case VIII.—A man, aged forty years, on the evening of election day, after receiving pay for his services for the day, proceeded to a restaurant to procure, as he said, "a square meal"; suddenly he became deeply cyanosed, showed difficulty of respiration, and fell to the floor. Before help could reach him he was dead. At the autopsy a large piece of meat was found lodged partly in the pharynx and partly in the larynx. There were areas of livor mortis scattered all over the body externally, and the internal organs showed the usual lesions found in death from asphyxiation.

Case IX.—A man, aged about forty, unknown, died suddenly in a restaurant while eating, and was removed to the morgue. After a complete autopsy, with the exception of the examination of the larynx, no sufficient cause for death was found. The history then being obtained that death had occurred in a restaurant, the larynx and trachea were opened and a large piece of meat was found extending from the pharynx into the larynx and partially through the glottis.

Case X.—An inmate of an insane asylum was sent to the morgue, with the history of having choked at the table. A piece of meat was said to have been removed from the larynx. At the autopsy the usual lesions in death from asphyxia were found, and an additional piece of meat was found in the trachea.

Case XI.—An unknown man was leaving a restaurant after eating his dinner, when he fell to the floor, became deeply cyanosed, showed difficulty of respiration, and soon died. He was removed to the morgue, and at the autopsy a piece of meat was found in the larynx.

Case XII.—A man, aged forty, had been eating at the free-lunch counter of a saloon after taking a drink. As he left the saloon he fell to the ground suddenly dead. At the autopsy a mass of crackers and cheese was found in the larynx.

Case XIII.—A negro child, aged about one year, was left with its bottle. The child's movements attracted its mother's attention. Then she noticed that the rubber nipple was missing from the bottle, and that the child was apparently struggling for breath. A physician was summoned, but before he arrived the child was dead. He, however, removed the rubber nipple from the larynx on the end of his finger.

Case XIV.—A patient was admitted to Bellevue Hospital suffering from compound fracture. It was decided to be best to operate immediately, and ether was administered. The patient vomited somewhat while under the influence of the anæsthetic, and suddenly stopped breathing; all attempts to restore respiration failed. The patient died. At the autopsy a mass of vomited matter was found firmly lodged in the larynx.

The cases in the second class—those of accidental suffocation of infants by closure of the mouth and nares—are exceedingly common, and the cause of death usually entirely escapes observation. The most common method of production of death in these cases is the "overlying" of infants while sleeping in bed with their parents. The usual history is, that the mother gave the child her breast during the night; she remembers nothing more; but when she awakened in the morning the child was dead. As has been noted by Tidy and by Jenkins, these cases, which occur for the most part among the lower classes, occur much more frequently on Saturday night or on a night after a holiday. At these times the mothers are likely to be partially stupefied by liquor; they are less thoughtful of their children and their sleep is deep. The mother turns partly on her side toward the child, the breast falls on the child's face, obstructing the entrance to the air-passages, and asphyxiation is gradually produced. The mother sleeps too soundly to be awakened by the movements of the child. Sometimes suffocation results from the bed-clothing being thrown over the child's head, or from its slipping off from the pillow underneath the clothes. These cases are too common to be mentioned in detail.

There are also many peculiar forms of suffocation occurring in infants and children, of which the four cases detailed below are good examples; the cause of death in such cases is often apparent:

Case XV.—Two children slept together in a crib: one was three years old, the other about five months; in the morning the elder one was found lying across the face of the younger, and the latter was dead.

Case XVI.—A child, aged six months, was left by its mother sitting in a high chair. The chair was a combination high chair and carriage, was placed on rather a broad platform (so that it could not be turned over easily), and under this platform were wheels; connecting the two arms of the chair in front of the seat was a guard to hold the child on the seat; the mother had left the child sitting in the chair, and when she returned, at the end of a few minutes, found the child dead, suspended with its face resting on the seat of the chair and with the occiput under the guard.

Case XVII.—A woman, aged twenty-five, an epileptic, fell from a chair with her child in her arms; she was found a short time later in an unconscious condition, overlying the child, which had died from suffocation.

Case XVIII.—A child, aged about eight months, was left alone with a handkerchief to suck; the parents returned after three quarters of an hour and the child was dead, having drawn nearly the whole handkerchief into its throat; vomiting had thus been produced, and this, with the handkerchief, had caused suffocation.

Case XIX.—Two negro infants were left sleeping quietly in a bed made upon some chairs at 3 A. M. by the woman having charge of them. At 6 A. M. they were found dead, covered over by the bed-clothing. The circumstances attending the case showed that death was accidental (Dr. Weston's case).

Cases of the third class—those of accidental suffocation of epileptics during convulsions, and alcoholics during profound intoxication—are comparatively common, and the cause of death when the detailed history is known is apparent. The nature of death, however, is very likely to escape the observation of physicians who are not accustomed to dealing with medico-legal cases, as they do not ascertain, as a rule, by careful questioning, the details in the history.

The history in all these cases of suffocation during epileptic convulsions takes one of two forms:

1. The patient falls on his face in a convulsion and remains lying in such a position that the mouth and nares are closed, or while lying in this position something is drawn into the larynx.

2. Patient has a convulsion while in bed, and during it turns over on the face and remains lying in this position during the unconscious stage, and thus becomes suffocated.

A number of cases are detailed below which illustrate the method of death in this class:

Case XX.—A young man, aged twenty-one, after spending the evening freely drinking with his companions, was found the next morning dead in bed, lying on his face. His companions, who were in the same room, had heard no disturbance during the night. The autopsy revealed only the lesions usually found in death from asphyxiation, and it was only after careful inquiry, directed by these lesions, that it was discovered that he had been found lying on his face in the bed. A small nodule was found in the dura on the left side; possibly owing to this or to the effects of alcohol, an epileptiform convulsion had resulted, and death was thus produced from suffocation.

Case XXI.—A girl, aged twelve, an epileptic, was found by her family in the morning dead in her bed, lying on her face.

Case XXII.—A young woman, aged twenty-one, an epileptic, was found dead in her bed in the morning, lying on her face.

Case XXIII.—A girl, aged eighteen, with the same history.

Case XXIV.—A woman, aged thirty-five, an epileptic, was found in the evening by her child on its return from school, lying on her face on the floor dead.

Case XXV.—Young woman, aged twenty-eight, an epileptic, while passing from one room to another quickly, during considerable excitement, suddenly fell on the floor on her face, and when assistance reached her, several minutes later, was dead.

Case XXVI.—A German, aged thirty-five, an officer's servant, during severe depression attempted suicide by shooting himself in the head. The ball lodged in the brain and was found there encapsulated years afterward. After this he became epileptic, and while vomiting, during a convulsion, asphyxiation was produced by the passage of food into the larynx.

Case XXVII.—A noted case has been reported by Dr. Janeway of death from suffocation in an epileptic who had a convulsion in a stable yard, and, falling upon his face upon the ground, was suffocated by manure drawn into his larynx. At the autopsy the larynx was found closed by masses of manure.

Case XXVIII.—A young man, aged twenty-three, an epileptic, was found dead in the morning, lying partly on the cot on which he slept and partly on a chair. The imprint of the cane seat of the chair was on the right side of his face and neck, and the discoloration here corresponded to the opening in the cane bottom of the chair on which he rested.

The face was deeply cyanosed, and at the autopsy nothing was found excepting the lesions common in death from asphyxiation.

Case XXIX.—A young man, an epileptic, went out at night into a stable yard to defecate. Just after completing the act he apparently fell forward in a convulsion, with his face downward, into a watering trough, which contained water only four or five inches in depth. Here he was found some hours later dead.

Death while a person is in a state of profound intoxication is less frequent than death during an epileptic convulsion, but its mechanism is the same. The following case illustrates this form very well:

Case XXX.—A German man, aged thirty, came home greatly intoxicated and threw himself prone on the bed. He was found dead in this position some hours after by his friends. Death had resulted from suffocation.

The cases grouped under the fourth head—those of submersion, strangulation, inhumation, etc.—form a separate class; the cause of death is usually apparent, and their consideration will be omitted here.

In conclusion, the following remarks are suggested:

1. Accidental suffocation is a common cause of sudden death, especially in children, and the cause of death usually escapes recognition.

2. Death produced by the lodgment of foreign bodies in the larynx or trachea occurs rapidly, and is sometimes almost instantaneous. The foreign body may be liquid as well as solid.

3. When death is instantaneous, it is probably the result of reflex inhibition of the heart's action.

4. In children the foreign body is usually some plaything that has been placed in the mouth, while in adults it is almost invariably an alimentary bolus, frequently meat.

5. The accidental suffocation of infants in bed by the bed-clothing and by "overlying" is a very common occurrence among the lower classes.

6. Death often results from suffocation during epileptic convulsions and during profound alcoholic intoxication.

58 East Twenty-fifth Street.

THE BRANDT REMEDIAL METHODS FOR PELVIC AFFECTIONS.

By GEORGE H. TAYLOR, M. D.

The communication of Dr. J. H. Boldt in the June number of the *American Journal of Obstetrics* explaining and advocating certain unique manual processes for the cure of affections of the contents of the female pelvis appears to invite examination, perhaps criticism. I will therefore proceed to bestow such notice on the remedial system referred to as its pretensions seem to call for.

The purpose of Dr. Boldt's article is to show the remedial power as well as the availability of *local massage* and allied manual methods for removing malpositions, congestions, functional irregularities and defects, and even more severe and advanced pathological conditions of the uterus and its appendages.

It is due that reasons be given why any reference to the subject introduced by Dr. Boldt's article is required. The peculiar practice described at length and with sufficient minuteness by Dr. Boldt was ostensibly inaugurated by T. Brandt, a non-medical Swede, the author of a thin volume, of which Dr. Boldt's communication is a *résumé*. The curative plan shown may appear plausible and even practical to the inexperienced and to those inclined to medical novelties. Positive and vehement assertions in medical matters, especially when backed by a formidable array of

successful cases, readily usurp the place of scientific statement and real merit. A tendency to accept and follow authority, or what seems such, is an instinct often insufficiently held in check by the reflective powers.

A conspicuous evidence of this tendency is now before me. A book just published from the pen of Dr. Herman Nebel at Wiesbaden, Germany, not only strongly advocates the Brandt system, but cites a long list of presumably respectable physicians in that country who have wholly or in part adopted in actual practice the same remarkable curative methods for the special class of cases before mentioned. This shows the importance of an intelligent presentation of the difficulties which the Brandt and similar methods have no adaptation to overcome and which *must* remain to torment both victims and advocates.

A further need for comment arises from the liability of the casual reader, who finds it impossible to keep himself "posted" on all phases of medical subjects, to confound the principles and methods set forth by Brandt with certain others which are in fact diametrically and unreservedly opposed thereto. It will become necessary in the course of the present article to give an intimation at least of the nature of these opposing principles.

History repeats itself even in affairs of the female pelvis. The Brandt system, if such it may be called, is devoid even of the questionable merit of novelty. Remedial processes substantially identical with those described by Dr. Boldt and Mr. Brandt, with such elaboration of detail, were, to my personal knowledge, much in vogue forty years ago in this country. It may not be without interest, perhaps may combine entertainment with warning, to advert to a bit of this history.

The inception of a practice of local "massage" for remedying various ills of the generative intestine dates back to the appearance in this country of the elder J. H. Bennett's book on the uterus, which was 1850. This work was extensively regarded as affording the last words to be said on what has since become developed into the many-sided and almost unlimited subject of gynæcology. Bennett's local methods of uterine therapeutics were generally adopted and often administered with more vigor than discretion. These methods were, of course, subject to "improvements"; among these improvements were local "massage" and a multitude of allied processes which were regarded as modes of securing the same effects. Afterward local massage became a practical substitute for, rather than an auxiliary to, direct medication of accessible portions of the generative intestine. Under the prevailing hypothesis of the nature of diseases of these parts of the body nice questions of ætiology were not troublesome.

Then, as now, there was abundant scope for the uterine specialist, for then, as now, there were women who preferred remedies to preventives, who preferred the chances of "cure" to the immunity offered through a wise discretion as to self-care. No one supposes that the average chronic "female disease" is inevitable; but, unfortunately, the avoidance of this class of affections has been and is but little discussed. Uterine specialists exist in response to the perennial demand, and the demand must continue till displaced by exemption, arising from the intelligence necessary for every woman on this subject.

At the period referred to, chronic uterine affections assumed a degree of prevalence typified by epidemics. Establishments devoted principally or wholly to this frail part of the female organism were judiciously located in this State and in parts of New England. Uterine defects and uterine cobbling were decidedly the *fad*. I knew of doctors without diplomas but with overwhelming patronage. The lack of authorization appeared to be no bar to success; and is not success sufficient evidence of both ability and merit? I was told of an omnibus line ending a short distance from this city which was literally crowded with women going to and returning from an eminent specialist. His methods consisted mainly in pushing up and properly poising the recalcitrant parts and executing at the same time interior local massage "from three to forty-five minutes," to be frequently repeated. One more reference, out of several I might give, will complete the surfeit of the reader and show the ease with which a certain kind of popularity has in times past been acquired. This specialist had a large establishment in a central part of this State. He had no medical or much other education. The two hundred women almost constantly present for years received personal attention from himself, assisted by one or two female helpers. His processes are well described in Dr. Boldt's article. He withdrew from practice, without diminution of patronage or popularity, only when his pecuniary ambition had become fully gratified. These facts were derived in part from personal interviews with the "doctor," in part from ex-patients. Other establishments, including the uterine specialty with a broader pathological scope, added the therapeutic attractions of electricity, various kinds of baths, etc.

We may call attention to the intrinsic nature of the difficulties presenting in these cases of disease and malposition of the pelvic organs, the better to understand the adaptation and want of adaptation of "massage" and other remedies for their removal.

Can poising the uterus, however dexterously, upon the tip of an operator's finger, can maintaining it in such position "from three to forty-five" or any number of minutes, not forgetting due interior combined with exterior massage, afford any considerable and practical information as to *why* this organ so insists on taking a downward or lateral excursion; *why* it doubles upon itself? How does toying with these perverse parts check or reverse their erratic tendencies? How, even, can prolonged sustentation of the uterus in an elevated and natural position, supposed to be secured by instruments, unravel the mystery of the *causes* of dislocation and deformity of the pelvic contents? Local "massage" sustains nothing; the pessary is only thrust between organs and parts; the supporter is buckled outside the same region; but how does either add to the physiological sustaining power? They only *seem* to the uninquiring to do so, but without scientific warrant. The downward tendency is not abated, only obstructed by local barriers. These have no physiological adaptation to lessen the weight of the pelvic contents, which is evidently the same with and without so-called supports. Even though the fibers forming the

organs within the pelvis should, by massage or any other means, become increased in tenacity and contractile power, no *sustaining* power is assured thereby, because of want of mechanical relationship. To expect the uterus, ovaries, and tubes to hold themselves up through an exertion of their own intrinsic mechanical power is like inviting a man to lift himself over a fence by the straps of his boots.

Divulsion of morbidly adhering parts is said by Brandt to be achieved by his system of "massage." Does this strenuous result give the least assurance of removal or even abatement of morbid continuous contact? Or that the same consequence from the same cause is not imminent? So, too, mechanical straightening of an incurved uterus, removal of cervical stenosis, and the crowding into place of a fugitive ovary are but temporary expedients, and, however frequently repeated, can in no degree diminish the erratic tendencies and habits of these respective parts. The unsubjugated organs will continue to manifest mechanical improprieties, will stray in forbidden directions, and get themselves figuratively ground between upper and nether millstones. The simple fact that there is no room above, or in any other location than that assumed, is strangely overlooked.

Similar difficulties are encountered in attempts to correct morbid conditions affecting the substance of the pelvic contents. We may pertinently inquire, Whence the excess, both solid and fluid, of materials which, more than any other single fact, characterizes the morbid state of these parts in its inception, development, and differentiation? Is quality as well as position independent of exterior influences, that its aberration should permit of remedies essentially local in their effects? Do gentle "squeezing," "malaxation," dexterous manipulating, and frequent coaxing of the generative intestine in some inexplicable and mysterious way engage the collateral circulation, and so open thereto a broader and more active connection? Are the chemical qualities of the local ingredients (always suspicious in disease) greatly improved by local massage? If so, what prevents immediate return of degeneration on suspending the fructifying agent?

Above all, are the means in question effective for, or do they even conduce to, a substantial and permanent re-enforcement of the vito-mechanical processes engaged in the normal return from the pelvic organs of their venous blood, and with it all ingredients whose prolonged presence is unwholesome?

But a fair estimate of the difficulties in the way of the Brandt system, and of other systems having similar purposes and limitations, does not end by proposing negations. We should note the injuries, positive and probable, which they are capable of inflicting; for, though healthy organs may not directly suffer from the processes described by Brandt, it must be admitted that the frequent repetition of such handling might prove rather rough for those in an unhealthy condition. The thinned walls of the distended capillaries, which have lost their contractility and bear but a slow and turgid stream, are not able to resist forcible mechanical impressions. Only such motor causes as operate *at* and *beyond* the venous outlets of the local vessels can be mechanically advantageous. Local massage can not extend its influence in any effective degree to the point where, if anywhere, it is required. Inferior degrees of the process are supererogatory or injurious, for renewal of local fluids and local nutrition necessarily depends on the facility of the venous exit. The tendency to deterioration of the pent-up local fluids can not be averted by merely local measures, however deftly applied.

Other difficulties inhere in the local plan under consideration. Whether such treatment be regarded as affording local stimulation, incitation, sedation, or other nominal effects, the production of these theoretical benefits is by no means the limit of its influence. Other effects, counter to those desired, inflicting far-reaching evil consequences, are necessary coincidents, not only defeating the main purpose, but even adding new pathological consequences; for the therapeutic plan described is a direct means of introducing and establishing new but unwholesome relations between the local parts and the organism at large, the reverse of those which obtain in health. The pelvis becomes a focus or center of the consciousness toward which the feelings and thoughts converge, in due response to physiological impressions. The pelvic organs are also resolved into a point toward which the circulation becomes actively directed, in further response to the same law. The local sensations and the local blood suffer morbid increase, and no counteracting influence accompanies these effects. This morbid action is maintained by the frequent repetitions of the local remedy which is usually demanded, and is therefore liable to become permanent. Even the most healthy pelvic organs can not long resist the disease-producing influences to which these parts are not infrequently subjected in disease.

The advocates of local massage usually insist on the coincident use of specialized, prescribed exercises, adapted to further the effects and to correct the deficiencies of massage alone. But, however elaborate and complicated these subsidiary processes may be, they fail to afford any suggestion as to the fundamental and continually operating sources of this class of affections, and little relevancy is apparent between the processes prescribed and the morbid conditions to be combated. Besides, the invalids suffering pelvic troubles are usually disabled, and therefore often incapable of voluntary action, and, as is well known, are liable to injury from volitional activities. All consideration for this class is, by the scheme referred to, omitted.

These difficulties are insignificant in comparison with the *misdirection* of the medical purpose and medical endeavor incident to the Brandt system; for pelvic affections of the ordinary chronic description are not self-produced and self-sustained or independent, but, from beginning to end, depend on adequate causes. These are the primary factors; the manipulation is secondary thereto and dependent thereon. The remedy under discussion is directed to the *secondary* factor; to *consequences* in place of *causes;* to subordinate features and evidences, while the potential and continuously operating sources on which these depend are quite omitted from consideration and remain unremedied. Pelvic affections, whatever their form of manifestation and however aggressive their symptoms, have their potentiality

in their sources. These sources should therefore become the chief object of medical solicitude, for remedies directed either to morbid location of the pelvic organs, to the tangible and ocular evidences of disease, to the local pain, or to all of these combined, may be powerless to reach the sources of these symptoms. There is, in general, a marked disparity between the immediate effects and the ultimate consequences of remedies employed on this principle. It is unreasonable to expect radical effects of the restorative order from remedies whose scope is thus restricted.

The full force of these statements appears only when the mechanico-physiology of the pelvis and its important organs become well understood. The location and the condition of these organs are dominated by environment to such a degree at least as to determine the state of their health, whether good or ill. The contents of the pelvis may be displaced in whole or in part by causes having their seat in the environment of these organs, and performing the function of sustentation, and not otherwise. Other ill manifestations have a similar source. These exist by reason of their nurture from environment, and necessarily disappear when their sources are removed.

The importance of environment is tacitly conceded whenever pessaries are thrust under and between the pelvic contents; and in a very odd way when the trunk space is diminished by a tight exterior band—both under the mistaken idea that the pelvic contents, in opposition to mechanical laws and common sense, may in these ways be urged upward. The first condition for securing an improved location for pelvic contents, or any of the parts thereof, is to provide space therefor. The same remark applies with equal force to deformities of these organs—such as retroflexion, and even stenosis.

The nature of the mechanism and the forces which at any time control the pelvic contents, solid and fluid—in other words, the pelvic environment—may be briefly shown. The lateral walls of the pelvis are bony, fixed, and not subject to change of any kind. In the inferior direction are the vagina, practically open and unresisting, and the perinæum, of only slight mechanical stability. These together are quite incapable of resisting any continuous impinging force; they, in fact, yield on moderate pressure. The only remaining boundary is the superior—that opposed to the inferior boundary of the abdomen. This boundary is nominal and does not exist as a practical fact, for the pelvic cavity is mechanically continuous with that of the abdomen; the two designations relate to parts of the one cavity of the trunk. The two classes of viscera, the abdominal or digestive and the pelvic, are in practical contact. And, as before intimated, the superimposed portions, by their facile glidings, turnings, wedgings, and insinuating moldings to the presenting irregularities of the pelvic contents, exercise a force on the latter which, when morbid, is shown in symptoms pertaining to the inferior and dominated parts. The dominating force is healthful or otherwise, according to circumstances. The nature of this force is made clear by a single suggestion.

If the abdominal mass be suddenly raised, say to the extent of an inch, does any one suppose that a vacuum would be caused in that perpendicular space as broad as the pelvic diameter? By no means. Any one understanding the action of a pump knows that an upward force is exerted on the *inferior parts* to a degree far in excess of that required to raise them into the occupancy of such space. The force in this way rendered active is, indeed, practically irresistible. The pelvic contents may therefore be easily and certainly controlled as to location by mechanical causes and conditions whose location is *above*, not below them.

This statement of physiological fact is undoubted as relates to health; that is, for all except the suffering class. The loss of health of the pelvic organs is therefore evidence of defects of the mechanico-physiological function whereby sustentation is naturally maintained. The restoration of such function is the *only actual* remedy possible, since other morbid phenomena are mainly derivative, secondary, and incapable of existence, except on condition of the defects described.

For those who have had no practical experience in rendering available for remedial purposes the source of power now referred to, further elucidation of the principles brought into action may be needful. It will be noted that spontaneous, constant fluctuations of the capacity of the cavity of the trunk characterize all animals, from man down, including all species. These fluctuations of space, produced by changes of exterior boundaries of the included space, are rhythmic, and synchronous with inspiration and expiration of a corresponding amount of air. These fluctuations do not cause interior vacant spaces, but measure the fifteen to thirty cubic inches of air to which they correspond. Not one fifth of the trunk capacity for fluctuation is usually called into use; there is hence an *enormous reserve* of mechanical capacity and of the forces which control it. In birds the mechanico-anatomical conditions are such that the exterior fluctuation is almost wholly at the posterior part of the trunk, the portion corresponding to the perinæum in other animals. In quadrupeds the lower abdomen, including the pelvis, which is an offset from the abdominal cavity, engages in the constant rhythmic fluctuations. This is very obvious when the creature is at rest or in moderate exercise. The whole trunk engages in increasing the amount of fluctuations of the space it includes when under the stress of vigorous exercise. In neither case are these fluctuations limited to the chest.

The location of the fluctuating area, and consequently of adjacent interior parts, is easily seen to be different in the persons of women suffering from pelvic diseases, pelvic malpositions, in all ruptured persons, and in those liable to fall under these categories. In these cases the rhythmic movements of exterior fluctuation of the walls of the trunk are both restricted and perverted. The most casual observation shows that in all examples of either of these cases there is little if any movement of the inferior portion of the walls of the trunk. The non-fluctuating area includes the lower abdomen, and consequently the pelvic space, which is a mechanical offset therefrom.

The respiratory rhythm and fluctuation of trunk-space is, in pelvic diseases, morbidly restricted to the upper por-

tion of the trunk. It fails to extend through the mass of its contents, and to include the pelvic viscera. But few of the muscles normally adapted to that use engage in the act. The lower abdominal and the pelvic contents are left motionless, while the restricted movements are morbidly transferred to the opposite extremity of the common cavity—that is, to the apex of the chest.

The above-described perversion and restriction of the natural and necessary action of the organic mechanism entail the disadvantages which result in morbid position and morbid phenomena.

The fluctuations of space within the cavity of the trunk bear a close resemblance to the action of a pump, and may be described as a continuous *lift*. All organs within the cavity of the pelvis are subjected to this lifting force. It affords sustentation to these organs and maintains wholesome mechanical interrelations between them. *As long as this act supplies due and constant upward tension, malposition and deformity can not exist.* The remedy for morbid location of the pelvic contents is hence to supply the upward tension which is naturally due them.

But it is not enough that sustaining energy be supplied to the contents of the pelvis. There is practically no vacant space into which the pelvic contents can possibly ascend till such space is provided. The uterus and ovaries can not be impelled by physical force into preoccupied locations. They will pass into such positions only in proportion as the parts above them recede. No other force is required.

It follows that the sustaining force, to effect the desired purpose, must extend equally to the abdominal contents; in fact, the efficient sustentation reaches the pelvic contents *through* the abdominal. The whole mass of the common cavity engages in the fluctuating motion superinduced by the muscular walls of the trunk.

The natural, incessant, mechanical fluctuations of the walls of the trunk at their inferior boundary, as above described and as witnessed in the lower animals and the healthy of the human species, have a further physiological purpose not less important than that above shown. By this mechanical action a constant and perfect *drainage* of the pelvic contents is secured. It is in vain to expect the return of health in these parts while the return circulation is imperfect and obstructed.

The venous blood, and indeed all excess of local interstitial as well as vascular fluids, are, by the means described, returned to the general system. The influence of the same vito-mechanical acts extends to whatever morbid ingredients these fluids may bear. The return circulation from both the head and the pelvis is secured by essentially the same mechanism. Neither part has control of its own venous contents; these in both cases are dominated by mechanism at a distance, urging the whole venous mass of blood toward the common center. The mechanical influence extends, when its degree is normal and healthy, to the remotest capillaries, and maintains them clear of obstructions.

The mechanico-physiological facts above set forth, so far from being obscure and open to question, are, on the contrary, patent to all observers. They are too common and well known and universally accepted to invite opposition or even attention. Their acceptance, however, affords a complete rationale of the mechanical control of the pelvic mass and parts and of the pelvic fluids. The action of this mechanism is functional; it extends to and is unequivocally connected with the cavity of the pelvis. The function described maintains the position of the organs of the pelvis as a mass and as separate parts. It also maintains the nutritive activities of the same organs by withdrawing their venous circulation, which is the indispensable condition for admission of the arterial. The conclusion is irresistible that defects of this raising and sustaining function result in defects of position—that is, malposition of parts; and that defects of local nutrition, through lack of insufficient change of local fluids, inevitably result in nutritive perversion, or its synonym, disease.

It is not difficult to understand the commanding therapeutic value of the physiological facts and principles above explained. But persons with only the slight acquaintance with them here afforded, and no experience adapted to confirm them, may be forgiven if they harbor some doubt until such facts and principles have been verified, if possible, through personal experience and by adequate tests. The mechanico-physiological function brought to view is practically identical with that of respiration, and consequently beyond question. What the inquirer wants to know is whether the power and the scope of the organic mechanism extend in fact to the interior of the pelvis; and whether, if this be the case, such power is both adapted and adequate to control the position and the condition of the pelvic organs; and whether such control is capable of transforming the pathological into a physiological state. It is further desirable to know whether these principles are susceptible of being carried out, proved, and confirmed by actual practicable processes, which effectually raise to and sustain in natural position the previously depressed deformed parts fixed by morbid, perhaps old, adhesions. It is, again, of the utmost consequence to learn whether the pent-up, restrained, deteriorating fluid contents of these local parts may be sent freely along their natural channels and become submitted, with that of all parts, to the powerful chemistry of the whole organism. *To all such inquiries I give an emphatic affirmative reply.*

Many experienced physicians join me in this affirmation. They have reduced to successful every-day practice the principles herein set forth, and with most unalloyed satisfaction. They have found their former methods in great degree superseded, substituted by those more radical and permanent. As for myself, after being well trained in the ways of the brightest and best of the lights of gynæcology now departed forever, these ways and methods were gradually displaced by those arising from a broader consideration of physiological facts. The mechanico physiological methods, as they developed, proved to be both speedy and positive as well as permanent in their effects. My personal test of the merit of the principles here presented extend over thirty years, and include the severest and least curable forms of cases not remedied, and often irremediable, by any less direct and thorough curative methods.

To assist the inquirer to a more vivid and comprehensiv

estimate of the mechanico-physiological methods for pelvic affections, I may be indulged in making a further exposition of them. Not only is the pelvic cavity at the base, and in one sense a part of the abdominal cavity, but its walls may easily be conceived as being extended on all sides so as to be continuous with and include those of the base of the abdomen. Being therefore sections of the same parts, they are necessarily subject to the same laws and functions.

It will be seen that the extension to which attention is now invited includes the region of *hernia*. An analogy between hernia and pelvic affections becomes evident on due reflection. The intestine or omentum in the protruded sac parallels the morbid descent of the pelvic contents. The two are, in fact, quite the same, the pelvic organs obscuring the misplacement of the overlying intestines. Both are consequences of unsustained weight of digestive organs. In the one case an artificial receptacle is formed by violent distension of a portion of the wall; in the other case the receptacle is ready-formed and natural. Both are parts of the same peritonæum.

Hernia occurs at points of least resistance. So does prolapse of pelvic organs. Hernial protrusion is caused by *persistent* pressure of a knuckle of intestine, due to immobility of the abdominal mass; prolapse of the contents of the pelvic cavity has the same antecedent condition. Strangulation of hernia results from defective communication between the contents of the sac and those of the abdomen; chronic disease of the pelvic organs betokens a similar lack. The very narrow neck of hernia renders the obstruction more complete and the symptoms more acute than is incident to the pelvic superior opening.

The nature of the mechanical problem presented in both strangulation of hernia and the suffering pelvic contents may now be separated from other considerations, and the remedial needs may thereby be better understood. The problem is not what it is ordinarily assumed to be. It is *not* a problem of mechanical pushing in and holding up of merely the insignificant amount of obtrusive flesh, but of restoring pre-existing physiological and mechanico-physiological connections—of re-establishing normal relations of parts, all of which are within the peritonæum.

Defect of those spontaneous organic motions which inhere in all healthy animals during life is the potential factor or cause in both classes of cases. The *restoration* of the normal degree and form of the same actions is the indispensable condition of cure; and for this there can, in the nature of things, be no complete remedial substitute.

This spontaneous organic motion is subject to augmentation as well as restriction.◦ The former is remedial, as the latter is the opposite. Through artificial devices and methods the fluctuation of capacity of the trunk may be enormously increased. The power which urges upward the contents of the trunk, including those of the pelvis, then becomes very much in excess of what is required to draw up the retroflexed uterus, to divulse adhering parts, and to return the escaped, strangulated intestine to the abdominal cavity, in spite of the size it may have acquired and the resistance of the canal through which it must repass. Should the reader desire the practical data, enabling him to verify the above statements, he will be provided with such in the form of a monograph (gratuitously) by making application at 71 East Fifty-ninth Street, New York.

The fact that pelvic affections of women are usually very slowly acquired and chronic does not affect the nature of the essential defect, or the nature of the means adapted to effect their removal. This fact only emphasizes the necessity of *cultivation* of the defective power to raise it to the desired standard. Remedial attention bestowed on subordinate factors or consequences of the initial defect are necessarily incapable of reaching the dominating factor. The propriety of this class of remedies, mainly palliative, is subject to the judgment of the physician.

To aid the inquirers to greater familiarity with the principles of the mechanical order involved in hernia and ill conditions of the pelvic organs, I will point out further mechanical analogies. The walls of the cavity of the trunk may be represented by the bulb of a common syringe. An indentation by the fingers of such a bulb excludes its fluid contents to an extent equal to the indentation. The removal of the pressure allows the force residing in the instrument to draw up the contents of the pipe or neck. If the bulb has a very thin, unresisting area, a defect near its neck, that area would bulge out on compression of other parts, especially if the pipe be obstructed; the same area would, by its oscillations, indicate all variations of degree of compression. No one would doubt but that all these changes of form would exactly indicate and be due to corresponding changes in the motor source, which in this case is the changing pressure of the fingers and the contents of the cavity. The outward impulsion of the thinned part of the bulb practically removes undue pressure from the whole remaining interior. So, too, when removal of pressure of the fingers allows the elastic force to assert itself, such force becomes manifest only at the protruded part, which is drawn in to the same extent and by the same force as caused the outward protrusion.

Let, now, this weakened and yielding portion of the bulb be conceived as so changed in shape as to constitute a true sac and neck. It will be readily admitted that it is still a part of the common cavity, and that the force, which for convenience rather than accuracy may be called suction, extends to the fluids contained within this branching sac, through its neck, in precisely the same degree as though there were *no* neck. Moreover, this point offering no resistance, the whole motor energy and motor effect of the elastic bulb is manifested here; and should the pipe be closed, the extended portion of wall would instantly be sucked in—returned. We may next conceive the transverse area of the neck and its communication with the sac as being indefinitely small—less than the diameter of the finest needle. This supposition would make no difference with the nature, or the amount, or the direction of the forces engaged, or with the effect of suction on the fluid contents. There is still a communication between the sac and the abdominal cavity by means of and through the *wet* tissues, even in the absence of pervious vessels. The least difference of pressure in the two cavities causes transfer of fluid *inward*, as previously it did *outward*. Strangulation does

not obliterate, but only obstructs communication, and indicates the immediate need of reversing its direction. The moment the experimenter applies this fact to practice he obtains direct evidence, through sight and touch, by the cessation of vomiting and of pain, that transfer of fluids is progressing. The observer will remark the very insignificant amount of solids in the sac after drainage of its fluids and the ease with which these slip back through the neck, however tortuous its cause or sharp the constricting pillars.

Hernial cases, which are more visible, tangible, and imminent than those appertaining to the pelvis, demonstrate more clearly the actuality, and even the great excess, of uplifting force, easily and quickly available, and that the usual obstacles are insufficient to resist its remedial efficacy. But *pelvic* cases, in which malposition is symbolized by hernial protrusion, and ill-condition by strangulation, are in general very chronic. This fact, to a certain extent, modifies the purpose of the remedy. An adequate uplifting and suction force is still demanded; but there is also required such increase of the natural mechanico-physiological powers which produce these effects as can be secured only by due cultivation of the instruments of this force. Nothing less is worthy the name of "cure" in these classes of cases.

The mechanico-physiological and the mechanico-pathological relations of the contents of the female pelvis will now admit of distinct and intelligible statement.

No distinct mechanical supports of the contents of the pelvis exist in anatomy, and none are required. Malpositions and ill-conditions do not occur in consequence of such deficiency, nor can local ill-conditions of the pelvic contents be rectified by an artificial supply.

The "strengthening" of the pelvic organs, were this possible, by local massage, or remedies having a similar purpose, can not, in the nature of things, reach the *sources* of the local manifestations, which exist in environments, and alone are, therefore, incapable of securing permanent results.

Sustentation of the contents of the female pelvis is, on the contrary, *functional* and *automatic*. It does not reside in or appertain to the sustained organs, but exists in their environment. The same physiological facts have equal application to conditions as well as positions. Both are dominated by forces exterior to the organs imperiled.

The amount of mechanical force latent in the mechanism of the organism is greatly in excess of that needed for restoring natural and desirable position of pelvic organs. To convert the *available* into *sustained* and *constant* force adapted to the same uses requires due cultivation of the instruments of such force by art.

The remedial aim in these cases should be to restore the natural degree of fluctuation of space in the cavity of the trunk; to secure this fluctuation of space at the *inferior portion of this cavity*. This necessarily causes its diminution at the opposite or upper end of the same cavity; a transfer of the involuntary organic act from the top to the bottom of the common trunk cavity. Medication unrelated to this purpose is proper to the extent that local palliative medication is legitimate.

WHAT IS ACCOMPLISHED BY THE USE OF DIGITALIS IN CARDIAC DISEASE?*

By EGBERT LE FEVRE, M. D.

In bringing before you to-night this well-worn topic I feel almost like offering an apology. Still, at times it seems necessary to review the grounds of our beliefs, and have clearly fixed the limitations of the power of the different remedies to combat the effects of organic diseases.

The heart is an organ whose parenchyma consists of the peculiar fibers that have the characteristics of both striped and involuntary muscles, and the function of the organ is to propel the blood through the systems over which it presides. The muscular fiber may be diseased or the mechanism may be altered, but, until the heart is unable to so distribute the blood as to meet the requirements of the system at large, the patient is, in a great majority of cases, ignorant of any morbid process.

In common with all muscular tissue, that of the heart has the inherent tendency to increase in size and strength when the work that it is called upon to do is increased. That this compensating hypertrophy may occur, the nervous mechanism of the heart must be adequate, and the quantity and quality of nutritive fluid equal to the increased demands. In cardiac diseases this conservative process is the one thing to be desired, and, when obtained, to be guarded and kept to the point where the heart is able to so perform its function as to meet the fastidious and exacting demands of the organism.

To understand the action of digitalis in cardiac diseases, it is necessary to observe its effects upon the normal heart. When given in physiological doses, it increases the force and completeness of the ventricular contractions; a larger blood-wave is thrown into the vessels, while the number of beats per unit of time is lessened. If the doses are increased, "the systole becomes abnormally energetic, so that the ventricles become white as the last drop of blood is squeezed out of them," and the heart during diastole does not dilate uniformly, the contracted portions showing as white patches. Two theories have been advanced to account for the slowing of the heart by digitalis. According to the mechanical theory, the heart contracting more completely, a larger amount of blood is thrown into the aorta and pulmonary artery at each beat. As the escape of blood through the capillaries is not proportionally increased, with the subsequent heightening of the resistance in these vessels, each wave demands more power to force it from the ventricles, and the heart is slowed in accordance with the physical law. What is gained in power is lost in speed. If this was the true explanation, "then the curve of the sphygmographic tracing would be: Ascent very oblique, height of curve small, and line of descent very oblique also." The direct opposite of this occurs.

The advocates of the other theory claim that it exerts an inhibitory action on the heart through some portion of the nervous system. The experiments of Boehm, Dybkowsky,

* Read before the Society of the Alumni of Bellevue Hospital, May 7, 1890.

Peliken, and Ackerman prove that it is not through the pneumogastrics nor the spinal cord, as the heart was slowed by its use after the destruction of the cord and the division of the vagi or the paralyzing of their peripheral ends by atropine.

Wood has concisely stated the status of our present knowledge: "Digitalis in moderate doses stimulates the musculo-motor portion of the heart (probably its contained ganglia), increases the activity of its inhibitory apparatus, and causes contraction of the arterioles, probably by an action on the vaso-motor centers in the cord."

Does digitalis exert any influence upon those nutritive changes that produce hypertrophy or cause its restoration when the compensation has been ruptured? It was formerly supposed that the semilunar valves closed the openings of the coronary arteries, so that they were filled during diastole only. This has been disproved. The flow of blood in these arteries is increased in common with that in the systemic circulation by the augmented power of the systole. During diastole, the greater the arterial tension in the aorta the more rapid is the flow of blood through the cardiac blood-vessels, and the nutrition of the heart is proportionally increased. One of the most noted effects of digitalis is its influence in raising the blood pressure in the aorta.

"The branches and capillaries of the coronary arteries lie within the layers of the muscular fibers and are surrounded by primitive bundles of fibers, while the lymphatics lie between the layers." This peculiar arrangement has an important bearing on the nutrition of the cardiac muscle. Digitalis, by its action on the musculo-motor portion of the heart, causes a more complete contraction of these encircling fibers, forcing the blood into the veins and accelerating the extravascular circulation, producing nutritive changes analogous to those of the faradaic current on voluntary muscles.

Important as the above-mentioned factors are, the power of digitalis over cardiac nutrition can only be explained by the theory that it acts on the trophic centers and nerves, placing, as it were, the cardiac muscle fiber in a condition to appropriate the elements of the blood needed for its growth.

When the valvular mechanism is deranged the heart adapts itself to the change by the corresponding increase in power of those parts whose work is increased. The prognosis and treatment of valvular lesions depend on the orifice affected, the character and extent of the lesion, and especially on the effect that the modification in the movement of blood through the heart has on the *work* and *nutrition* of the entire cardiac muscle. Each lesion of the valves adds its own peculiar factor to the problem. In mitral stenosis without insufficiency there is rarely dilatation of the cavity of the auricle, as the pressure in the pulmonary veins is not sufficient to produce overdistension during diastole, even when the cavity is not thoroughly emptied during systole. Consequently, the primary result of this lesion is simple hypertrophy.

As long as the auricle is able to empty itself through the narrowed orifice, there is no interference with the pulmonary circulation, as regurgitation into the pulmonary veins is prevented by the auricular systole beginning in the circular bands which surround the mouths of the veins. It is only when the auricle is unable to empty itself that pulmonary engorgement is produced. In simple mitral stenosis there is no hypertrophy of the left ventricle. Until the hypertrophy fails to compensate there is no indication for the use of digitalis. Some have advocated the use of digitalis in this lesion on the theory that its inhibitory action allows the auricle more time to empty itself.

In mitral insufficiency the regurgitant current is forced into the distensible auricle with a pressure equal to the power of the ventricle. This, together with the blood poured in from the pulmonary veins, causes primary dilatation with coincident hypertrophy of the auricle. On account of the increased capacity of the auricle, there is forced into the ventricle an amount of blood sufficient to overdistend its cavity and add to its work in emptying itself; as a result, hypertrophy follows. The extent of ventricular hypertrophy, and whether or not it is accompanied by dilatation, determines the seriousness of the valvular lesion. The most important factor of mitral insufficiency is its effects on the pulmonary circulation and right heart. The blood that regurgitates through the mitral orifice, by partially filling the cavity of the auricle, prevents the emptying of the pulmonary veins. As a result, the tension in the pulmonary artery is raised, and more power is needed by the right ventricle to empty itself. To meet this demand the muscle hypertrophies, the pulmonary circulation is restored, and the mitral lesion is compensated for as long as the power of the right ventricle is sufficient.

When the compensation ceases, the failure is shown first by interference with the pulmonary circulation, and then by dilatation of the right ventricular cavity. If the dilatation is so great that the tricuspid valves can not close the auriculo-ventricular orifice, regurgitation follows, with retarded venous circulation, while at the same time the left ventricle is imperfectly filled and pressure in the aorta falls.

Digitalis can not cure the organic lesion of the mitral valves that causes these changes. When the work of the right ventricle is further increased by some intercurrent pulmonary disease—as bronchitis—digitalis, by its tonic action, aids the heart to meet the emergency. When the burden has become too great and dilatation is present, digitalis, by increasing the power of the ventricular contraction, restores for the time being the pulmonary circulation, and, by diminishing the relaxation of the cavities, the tricuspid valves again become sufficient to close the orifice. For these beneficial results to become permanent, the muscle of the right heart must again hypertrophy enough to recompensate the mitral lesion, plus the dilatation of the right ventricular cavity. Digitalis aids in this, but, above all, the nutrient fluid must be in quantity and quality sufficient for the increased demands of the enlarged muscle.

Uncomplicated aortic stenosis does not call for digitalis until the power of the ventricle fails. This is shown by an irregular action of the heart—an imperfect filling of the aorta, often accompanied by a mitral systolic murmur, which

shows that dilatation of the ventricle has occurred and the auriculo-ventricular orifice has been stretched to such a degree that the valves are insufficient. Digitalis must be given to restore the tone of the muscle. It must be carried far enough, if possible, to bring the size of the cavity to the point where the mitral valves will again close the orifice.

In aortic regurgitation the conditions differ from lesions at other valves. Normally the left ventricle at each contraction forces its contents into the aorta against a pressure of 250 mm. of mercury. In insufficiency of the aortic valves with diastole the blood is forced back into the relaxed and distensible ventricle with a pressure equal to a column of blood 3·21 metres in height. This, according to Pascal's law, exerts a dilating pressure on the entire ventricular wall. The size of the opening determines the rapidity with which the pressure in the aorta and that in the ventricle become equal. As the capacity of the auricle equals that of the ventricle, at the auricular systole six ounces of blood are forced by the hypertrophied auricle into the already filled ventricle. When the leak at the aortic orifice is at first small in amount, then coincident with the dilatation occurs the compensating hypertrophy, which, when perfect, counteracts the distending tendency of the two streams of blood. When the insufficiency occurs suddenly, or when the compensation is incomplete, then the hydrostatic pressure of the regurgitant stream soon overcomes the resistance of the muscle and produces so great a dilatation that the mitral valves become incompetent temporarily, relieving during systole the overburdened ventricle.

In this lesion there is constant danger of death from sudden dilatation and syncope. The safety of the patient depends upon the ability of the heart to maintain its hypertrophy. The lowering of the pressure in the aorta has a deleterious effect upon the circulation in the coronary arteries, so that there is in addition the danger of degeneration in the heart muscle itself from malnutrition.

Many writers maintain that it is dangerous to give digitalis in aortic regurgitation, as the tendency to death from syncope is increased by the lengthening of the diastole and the consequent increase in the amount of regurgitation. If digitalis merely slowed the heart, the objection would hold good; but with its inhibitory action it also has the power to delay the relaxation of the cardiac muscle, especially during the first part of diastole. It is this power which exerts control over the dilating pressure of the regurgitant stream and, by maintaining for a longer time the pressure in the aorta, increases the blood-supply of the cardiac muscle. In aortic regurgitation the dose must be as small as possible in order to obtain the desired therapeutic effect.

In treating the degenerations of the cardiac muscle independent of valvular disease two things are to be considered: 1st, to lighten the work of the heart; 2d, to increase its nutrition. Digitalis in these cases not only acts as a stimulant to temporarily arrest the failure of the degenerated muscles, but also produces nutritive changes. At the same time, by the action of the drug upon the blood-vessels, the tension in the aorta is raised and the work of the heart is increased. This can be counteracted, to a certain degree, by the use of the vaso-motor dilators.

In the cardiac dilatation which follows the hypertrophy caused by renal and arterial diseases, digitalis must be given with extreme caution, for, by its power to raise the blood pressure, rupture of a diseased artery (especially in the brain) may be induced. Although dilatation is usually the result of valvular lesions, or dependent on one or the other form of degeneration of the myocardium, still cases are constantly occurring which, in their auscultatory signs, simulate those of organic causation. They occur in those cases attended by extreme muscular debility and relaxation. The murmurs heard in the mitral area are due to imperfect or irregular contractions of the ventricle, which allow a temporary insufficiency of the mitral valves; or, by the stretching of the papillary muscles and chordæ tendineæ, the valves are carried too far into the auricle, an audible regurgitation being produced. Digitalis, by its tonic and trophic action, causes the murmurs to disappear, and, with good blood, may be said to cure the disease.

The beneficial effect of digitalis in that condition known as "irritable heart" may be explained by its power to strengthen the musculo-motor apparatus and render it less susceptible to reflex irritations.

TESTS FOR SUGAR IN THE URINE.*

By BRANDRETH SYMONDS, A.M., M.D.

In opening this discussion, the methods by which we detect the presence of glucose in the urine must first be considered, for it is upon the delicacy and accuracy of our tests that the value of our clinical investigations will depend. Nearly all the tests for glucose depend upon its property of abstracting oxygen in the presence of an alkali. Among these reduction tests, so called, are Fehling's solution, Nylander's solution, indigo-carmine, picric acid, and safranin. This reducing action is by no means peculiar to glucose among the constituents of urine. Of normal ingredients, uric acid, creatinin, and pyrocatechin possess it, the first to a slight degree only. Among the bodies occasionally present in the urine may be mentioned oxybutyric acid; urochloralic acid, which is derived from chloral; glycuronic acid, from camphor; turpenoglycuronic acid, from turpentine; Marshall's glycosuric acid; and Kirke's uroleucic and uroxanthic acids. Besides these, many drugs form reducing substances during excretion, such as morphine, chloroform, salicylic acid, cubebs, copaiba, glycerin, hydroquinone, and carbolic acid. Of these substances, some have a limited range of reducing power, while others affect all the tests mentioned. Although these reduction tests may be nearly faultless in point of delicacy, it is evident from what has been said that their accuracy is not great. To take them up in detail:

1. *The Well-known Fehling's Solution.*—This possesses all the disadvantages of its class, being readily reduced by other substances than glucose. It has the further disadvantage of spoiling rapidly, although Schmiedeberg's modification, in which mannite is used instead of Rochelle salt,

* Read before the Society of the Alumni of Bellevue Hospital at its first annual reunion.

is said to keep well. The ordinary solution has to be divided into two parts in order to prevent decomposition, and then mixed at the moment of using. This is certainly an awkward proceeding. On the score of delicacy it leaves hardly anything to be desired, as it will detect one twentieth per cent. of glucose in urine, though not very distinctly. In order to do this, the upper layers of the urine must be boiled and then a few drops of a proved sample of Fehling's solution are to be added. The upper layers are again boiled and the reduction occurs. It has been said that glucose is the only substance that will reduce Fehling's solution in the cold. This is certainly incorrect, for chloral will reduce it readily in the cold, and chloral is probably excreted in part as such.

2. *Nylander's Solution.* — This is a modification of Boettger's test and consists of 2 grammes of bismuth subnitrate and 4 of Rochelle salt, dissolved in 100 c. c. of a ten-per-cent. solution of sodium hydrate. On boiling with glucose, a dark-brown or black precipitate of metallic bismuth and bismuth suboxide is produced. It has the advantage over Fehling's solution of not spoiling. I have kept it in an ordinary colorless bottle exposed to sun and air during several of the hot months without any discoverable alteration. It is not so readily reduced as Fehling's solution, not being affected by chloral, pyrocatechin, or glycosuric acid. It is, however, less delicate than Fehling's solution, detecting only one tenth per cent. of glucose, and that imperfectly. The most delicate method of applying the test is to fill a test-tube about half full of urine and then add about one third of the solution. Boil the upper layers and note the reduction. Although less delicate than Fehling's, it is the only one of the reduction tests which I constantly employ. It is less cumbersome and gives results which are, I think, sufficiently good for ordinary clinical work. It is occasionally reduced by other substances than glucose. It is reduced by glucose in the cold, and also by normal urine.

3. An alkaline solution of indigo-carmine when boiled with glucose becomes decolorized, changing from blue to purple, then red, and finally yellow. This play of colors is due to deoxidation, and they can be restored in the inverse order by shaking the solution with the air and thus obtaining oxygen. The alkali used must not be caustic, for both potassic and sodic hydrate change the color without the aid of glucose. The one commonly used is sodic carbonate.

This test will readily detect very small quantities of glucose, but, unfortunately, is reduced by prolonged boiling with perfectly normal urine. Oliver maintains that it is perfectly reliable, but also says that urine normally contains half a grain of glucose to the ounce, or one tenth of one per cent., which can safely be denied.

4. The same objection applies to picric acid, which, when boiled with glucose and an alkali, is reduced to the dark-red picramic acid. This red color occurs also with normal urine, the creatinin which is regularly present being sufficient to develop it. On the score of both accuracy and delicacy, this test must be laid aside.

5. With safranin I have not had much experience. In the presence of glucose and an alkali the red color is changed into a dirty white. This alteration is produced likewise by prolonged boiling with albumin, though normal urine does not cause it. Whether it would be produced by glycosuric acid or some of the other reducing substances occasionally present in the urine I can not say. As it is a reduction test it seems reasonable to suppose that the change would occur. It is quite delicate, readily indicating one tenth per cent. of glucose.

6. In this class must be placed, I think, Molisch's test with alpha-naphthol or thymol. Into 2 or 3 c. c. of urine are put three or four drops of a twenty-per-cent. solution of alpha-naphthol in alcohol. Sulphuric acid is then added to an excess of three or four times the bulk. A beautiful violet color forms which, on large dilution with water, falls as a violet precipitate. If thymol is used instead of alpha-naphthol, a red color results, followed by a reddish precipitate. These colors and precipitates are readily produced in normal urine by this test, and Molisch of course states that normal urine contains sugar. In order to ascertain the worth of this method I took 2 c. c. of normal urine, which showed no reaction with phenylhydrazin, and obtained from it an abundant violet precipitate. I then took 2 c. c. of water containing one one-hundredth per cent. of glucose. On applying Molisch's method I obtained a violet precipitate about one fifth in amount of that obtained from normal urine. This, I think, is a crucial test and one that demonstrates the worthlessness of the method for clinical purposes. It is undoubtedly a delicate reaction for sugar, but it also reacts with other substances normally present in the urine.

All of these reduction tests have only a negative value, and for that some of them, such as Fehling's, can hardly be surpassed. Fehling's will indicate one twentieth per cent. of glucose, and I think we need nothing more delicate than that. But a positive result with any of them is valueless, since they can be so readily affected by other reducing substances than sugar which may be present in the urine. During the past year, as Examiner for the Mutual Life Insurance Company, of New York, I have had seven or eight cases in which Fehling's and Nylander's solutions were both reduced by urine, which urine, on subsequent examination by phenylhydrazin and by fermentation, was shown to be entirely free from sugar. I can recall one case in particular in which the reduction of Fehling's solution was equivalent to over one per cent. of glucose. Without further investigation these would doubtless have been regarded as cases of glycosuria, and on that ground would have been refused insurance. Frank Donaldson, Sr., has reported a more striking case, in which the precipitation of Fehling's solution was equivalent to over eight per cent. of glucose. Marshall subsequently examined the urine and isolated the reducing substance. This he called glycosuric acid, not because it has the remotest connection with glucose, but on account of the similarity of its action on Fehling's solution.

There are but two methods which give reliable positive results—fermentation and phenylhydrazin. In the former the urine is fermented and the carbon dioxide given off is collected and measured. A gramme of glucose when fermented will form about 250 c. c. of carbon dioxide at ordinary temperature and pressure. A very convenient appa-

ratus for collecting and measuring this is Einhorn's tubes. As urine will absorb about its own volume of carbon dioxide, and as yeast always contains a little sugar, the method is not very delicate. I think that about the best that can be alleged for it is its ability to demonstrate one tenth per cent. of glucose. Another application of fermentation is by taking the specific gravity before and after fermenting. This is even less delicate than the preceding.

The other reliable positive method is by the phenylhydrazin test. This was first devised by Fischer, and has since been strongly indorsed by von Jaksch and Ultzmann. The original method of applying it was to dissolve 2 grammes of phenylhydrazin hydrochloride and 1·5 gramme of sodium acetate in 20 c. c. of water. Then mix with 50 c. c. of urine, and heat in a water-bath for twenty or thirty minutes. Ultzmann, as reported by Bond, has modified it in a very simple way. According to his method, put in an ordinary test-tube about half an inch of the phenyl salt. This is a brownish-white, scaly substance, having a strong odor of aniline. On top of this put another half-inch of sodium acetate, and fill the tube half full of urine. Shake until the sodium acetate is dissolved, and then gently heat. When the whole mass is hot, boil from half a minute to a minute. This method is much less cumbersome than the original, and is nearly if not quite as good. In both methods albumin, if present, should first be removed by boiling and filtering or decanting, as it forms a sediment which may mask the result. The result of these manipulations is the formation of phenylglucosazone, which crystallizes out and can be found in the precipitate. This is a definite chemical compound, having the formula $C_{18}H_{22}N_4O_4$. It forms acicular crystals of a golden-yellow color, which can easily be recognized under the microscope. They have a marked tendency to collect in radiating clusters, or in sprays that resemble a feather or a twig of spruce, or in sheaves like those of wheat. They are almost insoluble in water, but readily soluble in alcohol. They fuse at 204° to 205° C. Similar compounds are formed with lactose, galactose, and maltose. None of these, except lactose, occur in the urine. The fusing point of phenyllactosazone is 200° C.—so near that of phenylglucosazone that it is valueless for ordidinary differentiation. But lactose occurs only in the urine of nursing women during acute suppression of lactation. Consequently its liability to interfere is very slight. Tyrosin forms somewhat similar clusters, but the crystals are colorless. I think it may safely be asserted that the crystals of phenylglucosazone are characteristic, and a positive indication of the presence of glucose. The limitation by lactose is so slight that it may usually be ignored. I have tried this method with a number of drugs which are excreted in the urine, and in no case have I obtained any similar formation. The list includes morphine, atropine, phenacetin, antipyrine, acetanilide, chloral, quinine, and chloroform. The presence of chloral is objectionable, because it forms an abundant precipitate of reddish-brown globules, which tends to mask the crystals of phenylglucosazone. These globules resemble those of phenylhydrazin, which are often found in the deposit, owing to an excess of the salt. They are freely soluble in alcohol, from which they redeposit on evaporation in the same form. As regards delicacy, this test can hardly be excelled. I have found distinct crystals in a urine which contained only one one-hundredth of one per cent. of glucose, but then only after standing for forty-eight hours. When glucose is present to the amount of one tenth per cent., the crystals can be seen within fifteen minutes after boiling by Ultzmann's method, but they are then quite small, and it is better to wait for half an hour. One twentieth per cent. can be discovered after standing three to four hours.

This method or fermentation should be employed in all cases where glycosuria is inferred from the examination of the urine alone. Otherwise we shall certainly be deceived at times by the behavior of other substances than glucose which give rise to similar reactions with the ordinary tests.

A CASE OF TREPHINING FOR PARALYSIS OF SPEECH FOLLOWING AN INJURY.

By J. D. JONES, M. D.,
Utica, N. Y.

Although I have to preface the narration of the following case with the humiliating confession that I erred in the diagnosis, still I believe that enough may be learned from it to justify its publication. During this, which may be termed an era of special activity in brain surgery, I believe that not only the successful and brilliant results should be published, but the failures, and worse than failures—the fatal results—as well. It is only in that way that we can arrive at correct statistics of the mortality of the operation and gain correct data as to when to operate and when to leave alone. Judging from the cases published in the journals during the last two years, one would infer that the operation was almost devoid of danger and that the results are almost uniformly successful. A note published nine months or a year after the operation would often tell a different story. I propose to follow that plan in this instance.

Mary B., aged twenty-six, single, of healthy parentage, had enjoyed previous good health, but was of questionable morals, and occasionally drank to excess. After a three-days' absence from home on one of these sprees she was found in an outhouse in another part of the city, unable to speak or move, but conscious. She was carried to the city hospital, where, according to her mother, she had several convulsions limited to the right side. I first saw her October 16, 1889, at her home, about four days after the receipt of her injuries. Her condition then was as follows: She had complete motor paralysis of the right leg and arm, the right side of the face was paralyzed, the tongue deviated to the right, she felt the prick of a pin over the paralyzed area, but sensation did not seem to be very quick, though no very accurate tests were applied to determine the degree of impairment. She could not utter a word except "No," which was the universal answer to every question. She appeared to be rational and to understand everything that was said to her. Her pulse and temperature were normal, and remained so to the time of the operation. There was a large

ecchymotic spot above and back of the left eye. There was no wound of the soft parts and no depression could be felt in the bone. There were "black and blue" marks on other parts of the body. There was a conclusive history of traumatism. That, with the location of the extravasation on the left side of the head, with the right-sided motor paralysis, and paralysis of speech, led to the diagnosis of pressure by a blood-clot, probably from a fracture of the inner table. She gradually recovered the use of the leg and arm, the former first, bnt, with the exception of the addition of "I can't" to her vocabulary, her speech remained unimproved. On two occasions she had attacks of transient delirium with hallucinations of sight, but they were not attended with any rise of temperature, and both subsided within twelve hours of their onset. She also had twitching of the right arm occasionally, which was controlled by small doses of bromide of potassium.

In the latter part of February, 1890, Dr. W. E. Ford, of this city, saw her in consultation with me, and agreed that the symptoms pointed to pressure on the center for speech and motor area on the left side by a clot probably, and advised an operation. Accordingly, the operation was performed on March 15th with the assistance of Dr. Ford, Dr. Schuyler, Dr. Weed, and Dr. Brown. The center for speech was located by the rules given by Dr. Dana in the *Medical Record* of January 12, 1889. The head was shaved and thoroughly disinfected. The skull was marked with the center-pin of the trephine before making the incision. A horseshoe flap, with the convexity directed downward and backward for drainage, was raised. An inch trephine was applied with the center-pin at the point previously marked on the bone. On removing the trephine after making a few quarter turns an alarming hæmorrhage took place from the hole made by the center-pin. We thought at the time that the screw had failed to hold the pin, allowing it to penetrate the bone prematurely and so wound a vessel in the dura. So the button of bone was hurriedly removed; the blood poured into the opening so freely that it was even then impossible to decide its source. The dura was opened, the finger introduced between the dura and pia, and the former pressed firmly against the skull; in that way the hæmorrhage was stopped. On subsequently examining the button of bone it was evident that the bleeding came from one of the large veins of the diploe, which had been pierced squarely by the center-pin, and it was the finger hooked over the mouth of this that checked the hæmorrhage. The pia mater was opened, but no clot was found. The brain tissue in this locality, however, was evidently diseased. There was no hæmorrhage of any moment from the dura or pia mater. As the brain tissue had been examined with the handle of the scalpel, no sutures were put in the coverings. They were simply adjusted. After all bleeding had been stopped, the wound was dusted with iodoform, a drainage-tube was introduced into the most dependent part, and the flap closed with interrupted silk sutures and an antiseptic dressing applied. She rallied well from the operation.

March 16th, A. M.—Pulse, 112; temperature (by the mouth), 99·5°. Vomiting freely from the ether. *P. M.*, pulse, 114; temperature, 100°; delirious.

17th, A. M.—Pulse, 120; temperature, 100°. Wound dressed. No discharge. It is evidently aseptic. *P. M.*, pulse, 112; temperature, 100°. She rested well during the day. Vomiting has ceased.

18th, A. M.—Pulse, 108; temperature, 100·2°. She was delirious during the latter part of the night. *P. M.*, pulse, 108; temperature, 100·2°.

19th, A. M.—Pulse, 102; temperature, 100·5°, highest temperature reached. Delirious during the night; appears dull this morning. Redressed the wound. No discharge. Removed the drainage-tube and introduced a twist of absorbent cotton soaked in a solution of bichloride (1 to 2,000) to keep the external opening patent. *P. M.*, pulse, 90; temperature, 99·5. Doing well.

20th.—Pulse, 88; temperature, 99·2°. Rested well last night.

21st.—Pulse, 84; temperature, 98·5°. During the night she had several convulsive seizures limited chiefly to the right side. In those I saw the twitching was confined to the right arm and right side of the face, but the right leg also was said to have been drawn up in some of them. The wound was redressed. The sutures were all removed, as it had healed firmly all around except where the drainage-tube had been. She was put on bromide of potassium (ten grains) repeated two or three times in the early evening.

22d.—She had one fit at eleven o'clock last night. Pulse, 90; temperature, 99·5°.

23d.—Pulse, 84; temperature, 98·8°. Doing well. She sat up to have her head dressed to-day.

24th.—Pulse, 90; temperature, 98·5°, and it remained normal after this. She looks bright. Her recovery has been uninterrupted since. By April 5th the opening for drainage had granulated even with the surface, and she was going about feeling well.

With regard to her speech. As I said before, her vocabulary was limited to "No" and "I can't," and she couldn't repeat a word spoken to her. I spent considerable time on various occasions trying to have her repeat some simple monosyllable. She would try hard for a while, then become irritable, and end with the invariable "No, I can't." On the third day after the operation she greeted me with "Good morning," and addressed me by name. She can now repeat any word spoken to her. She already has quite an extended vocabulary of names of articles of food, bedclothing, etc.—names she hears repeatedly and which she uses correctly. She also counts readily. I am unable to explain the connection between the operation and the improvement in speech, and simply relate the facts.

The most interesting point in connection with the case is the diagnosis. Was there any way of determining in this case whether the symptoms depended on pressure—as by a clot—external to the surface, or to a lesion of the cortex itself? We thought it was the former; it proved to be the latter.

Considering her age, with the history of an injury and with the ecchymosis in the position to explain the paralytic symptoms present, even in the absence of an external wound and such palpable evidence of fracture as depression, the presumption was certainly in favor of our interpretation of the symptoms, and the operation therefore was indicated and justifiable.

GIANT-CELLED SARCOMA OF THE FINGER OF UNUSUAL SIZE.*

By WILLIAM R. BALLOU, M. D.

The rarity of osteosarcoma of the fingers and the beautiful specimen which I will show with the patient from

* Read before the Society of the Alumni of Bellevue Hospital, May 7, 1890, and the specimen and patient shown.

whom it was removed, led me to present the history of the following case:

Mrs. L., Italian, aged twenty-nine, came under my care at Bellevue Dispensary on August 18, 1889, for the treatment of a large tumor of the left hand. The family history was negative, as was also that of syphilis or injury.

About a year and a half before, the first interphalangeal articulation of the left ring finger began to increase in size, but was not painful. From that time till the middle of July, one month before I saw her, it had remained of about the size of an English walnut, when it began to enlarge rapidly and developed spontaneous pain.

At the time she came under observation the tumor was nearly of the size of my closed fist, measured in its greatest circumference eleven inches, and involved the distal half of the left fourth metacarpal bone, the whole of the first and part of the second phalanges. The tip of the finger, as you see, projected from the mass of the tumor. It was generally hard, with some fluctuating areas which proved to be cystic in nature. The superficial veins were dilated and tortuous, and the growth had pushed the middle and little fingers widely apart, and interfered greatly with the use of the hand. Careful search failed to show any enlarged glands.

A diagnosis of chondrosarcoma was made, my belief being that it had at first been a chondroma of innocent form, which for some reason had taken on malignant action. Immediate amputation was advised, the operation to include the finger, its corresponding metacarpal bone, and other fingers if the growth was found to involve any other structures on dissection.

On August 20, 1889, the amputation was done under cocaine with the assistance of several of my students. The tumor was first freed from the surrounding structures and the metacarpal bone sawn through below the growth. The vessels were large and the hæmorrhage profuse. After their ligation the remainder of the metacarpal bone was removed with a *rongeur* forceps, a drainage-tube introduced, and the wound closed. It healed kindly, and a very comely and useful hand was the result. The tumor was kindly examined by my friend Dr. H. M. Biggs, of the Carnegie Laboratory, who pronounced it a beautiful specimen of giant-celled sarcoma springing from bone.

At the present time the patient is in good condition, has no pain, or the slightest suspicion of recurrence, and has almost perfect use of the hand.

102 East Thirty-first Street.

THE BORDERLAND.

By SARAH E. POST, M. D.

The interest in occult psychic phenomena seems on the increase rather than on the wane. *Scribner's Magazine* for March has a charmingly written paper upon The Hidden Self, by William James, brother to the novelist; while the Forum for April contains two papers of considerable interest—The True and the False in Spiritualism, by Mr. Hodgson, and a paper upon the relations of Hypnotism and Crime, by Charcot. Last year, too, we had a series of papers dealing with the usual phenomena of hypnotism in the *North American Review*.

The last-named series described experiments with which we are familiar. The patient having been thrown into the hypnotic condition, the operator, technically known as the agent, by means of the sense of sight or hearing or in some other clearly material way, communicated to him suggestions in the form of trains of thought with a natural conclusion or in the form of direct commands. As a result, the subject would believe absurd propositions, perform ridiculous actions, or even commit crime. In the course of these papers Mr. C. distinctly says that he has never succeeded in conveying suggestions in any but tangible ways. For instance, if the patient had his back to him he could not secure his co-operation without the aid of the voice. The influence of his mind, unaided by the ordinary senses, was unable to communicate or to impress itself upon the mind of the other; in fact, the tone of the statement made upon this point is such as to lead to the inference that the writer disbelieves in such unembodied transmission of mind force.

A curious point about hypnotics is that the person hypnotized is of a different disposition from the person unhypnotized. This fact is the feature of Mr. James's paper. In certain easily hypnotized persons it has even been found possible to produce two distinct conditions of hypnotization, so that the person has three separate lives or planes of consciousness, not any one of which infringes upon or is cognizant of the other. A still more curious thing, perhaps, is the fact that only one of these planes of consciousness wakes to activity at a time.

When hypnotized in the first degree the subject resumes memory and impulses belonging to this state at the point where they were dropped at the end of the previous séance. A similar resumption occurs when the subject is hypnotized in the second degree; and similarly, the unhypnotized individual knows nothing of what has passed during the other two phases of his existence and is a quite different person—a very stupid person, by the way, as a rule. Mr. James suggests that the familiar sensation of having been previously in the same place or surrounded by the same circumstances is perhaps due to the intruding of a second or hidden plane of consciousness into the affairs of ordinary life. He suggests also that dreams, often so erratic and contrary to ordinary experience, may be due to activity of this hidden self. As in the old German tales, the puppets and the playthings come out from their receptacles and hold high revel while sleep rules the master of the house.

Just here we would like to call attention to the fact that some hypnotics in France have been controlled by minds at a distance; they have been even incited to actions by will power exerted miles away; and this brings us to another phase of psychic control, the domain of telepathy. By the way, the word telepathy is not found in Webster's dictionary, edition of 1886. From an analysis of its root-forms, however, we arrive at the fact that it means to suffer or to experience from a distance or at a distance. Telephone and telegraph are similarly constructed words, telephone meaning to speak from afar; telegraph, to write from afar; and telepathic (we have not yet arrived at the noun telepath), suffering or experiencing from afar. In the line of these experiences comes the presentiment that some one approaches or is near. Instances have been given in which highly nervous invalids have even known the personality of the approaching guest by telepathic instinct. Mr. Hodg-

son suggests that the phenomena of clairvoyance and slate writing are of this character, the medium or slate writer really obtaining her ideas from the minds of those present. It is said that the agent in this case need not even have the matter by which the subject is impressed actively before his consciousness; he may at the time even be "thinking of something else."

We have then recognized as demonstrated phenomena, mind control by means of hypnotism and suggestion through ordinary channels, and mind impression or control either directly or by channels which we do not know. I do not, however, find recognized by any of these writers a third phenomenon which I am assured exists. This is direct muscular control by a foreign mind. In the case of certain hypnotized people it has been possible to slow the heart by telepathic suggestion on the part of the operator. These cases have never received an adequate explanation. Apparently there was no mental state in the subject which induced the inhibition; it was a direct result of control. To this example I can add a case of my own more fully reported in the *North American Review* for April, 1889.

The place was the sitting-room of a woman's boarding-house. None but women were present. The experiment was in the form of a game in the course of which the subject, blindfolded, found different hidden articles, the suggestion being supposably conveyed from the mind of the operator through her hands lightly laid on the subject's back. The subject succeeding in these ordinary manœuvres of the game, a more difficult test was proposed. The subject advanced to the middle of the room, bent her head and gave no further response, and the experiment was declared to have failed. The evidence carried by this series of experiments has to do entirely with that one which failed. Subjects being usually hypnotized, it is seldom we have the opportunity to get their side of the story. This subject was not, however, hypnotized, and her description of the experiment is as follows: "Learning that all that was required of me was to follow suggestions, I promised co-operation. I stated at first that I would make no resistance; that if the operator could make me know what I was to do by means of her hands on my back, I would do it. I further prepared myself by putting all ideas out of my mind, for I thought, unless I am alert and attentive, I shall not be able to understand what it is I am to do. My thought was that I might receive a finished idea or project which would outline what I was to do. Instead, during the earlier experiments, I felt nothing but a loss of equilibrium; I took steps in this direction or that to save myself from falling down. I do not remember the sensations which preceded or accompanied putting out the hand to grasp the hidden objects, but I found the things without knowing that I was looking for them. During the last experiment, however, I did have an idea, and it came about in this way. I advanced to the middle of the room in response to the loss of equilibrium as before. I bent my head and then commenced to feel a puckering up of the mouth, and I said to myself: 'I am afraid they are going to make me kiss some one. I hope not, for I shall not be able to do it.' Then I reasoned with myself about having so foolish an idea. I said to myself: 'Put it away or you will not be able to receive the impression they are trying to give to you.' I did then succeed in again abstracting my mind so that no memory of the kiss remained, but no further impulse came to me. I stood in the center of the room motionless, not even the loss of equilibrium reasserting itself." The subject had been directed to kiss one of the young ladies in the room; she had advanced to her side, but had remained standing, and the experiment was declared to have failed.

The subject was at that time at least a fairly intelligent person, and her evidence is perhaps as good as that of any which can be obtained upon these matters. The subject was positive that the idea of kissing followed the contraction of the orbicular muscle, and was apparently suggested by it. The muscular act, like those of the preceding experiments, was not induced by any idea or conscious mental effort on her part.

The proposition of muscular control by the intervention of a foreign mind is startling in its far-reaching importance. It will be borne in mind that the subject is undisturbed, is unconscious of control until it reveals itself by the finished act. Even then he or she may not be completely conscious unless the action excites repugnance in the mind. A whole series of experiences will range themselves under this heading if its existence be once admitted.

Undoubtedly the possibility of extraneous muscle control is in a high degree abnormal; it is one of the phases of hysteria. James defines hysteria as the power of concentrating or splitting up consciousness. By this process consciousness may be withdrawn from certain brain areas or independent realms of consciousness may exist within the same brain. While this faculty is undoubtedly rare among us, it is not rare among Eastern peoples, abstraction being there a highly prized faculty of the mind. Insensibility to pain and the various phenomena of stoicism can perhaps be traced to this source.

The mechanism of extraneous muscle control must be in the highest degree problematic, as it implies either a spiritual entity capable of taking possession of another's body, or some as yet unrecognized medium of force.

The applications of this power should be, like those of the phenomena of hypnotism, limited to therapeutic purposes. While in a state of health extraneous muscle control must be undesirable. We have heard of suggestion used for moral ends. The refractory boy or girl is gently hypnotized and persuaded to the adoption of wholesome ideas. But it will be recognized that the appeal is in this case to the mind of the subject. The phenomenon belongs to the first class of cases we have here considered. In the class now under consideration the appeal is directly to the irresponsible body. It is apparent that under ordinary circumstances nothing but harm can result from such control. We believe that in sickness, however, this power is and should be utilized for good. The "control" of the good doctor and good nurse is, I believe, often of this character. We are ourselves conscious of having controlled vomiting in patients by our own mental efforts at a time when the patients' mental processes were of too unreliable a character to be considered a factor in the result.

The value of moral ideas or prejudices also becomes very apparent in this connection. The subject in the experiment narrated interfered with the control from the fact that the action required was repugnant. Deep-rooted prejudices in favor of right living will be the best protection against harmful extraneous control.

NEW YORK, SATURDAY, JULY 12, 1890.

RECENT MEDICAL LEGISLATION IN NEW YORK.

Last winter an effort was made to secure the repeal of the act making it necessary for persons about to study medicine to pass a preliminary examination by the Board of Regents of the University, or under their direction. The effort failed, but certain modifying bills were passed, and have received the Governor's signature, effecting the following changes: 1. The examination, although still called "preliminary," may be passed at any time during the student's first year of study within the State. 2. It may be conducted by the college faculty "in accordance with the standard and rules of the said regents." 3. The examination is not required if the candidate possesses qualifications which the regents consider and accept as fully equivalent to those demanded in their examination. The regents were to meet on the 13th of June to decide upon these equivalents, and it was their announced intention to notify the various medical schools promptly of any conclusion at which they might arrive. According to the original act, the possession of a degree in arts, science, or philosophy from an institution duly authorized to confer the same exempts the holder from the examination.

The new medical practice act goes into effect on the 1st of September, 1891. Its provisions are substantially as follows: Three separate boards of medical examiners, each consisting of seven members, are to be appointed by the Regents of the University from nominees of the three State medical societies. One board is to represent the Medical Society of the State of New York, the second the Homœopathic Medical Society of the State of New York, and the third the Eclectic Medical Society of the State of New York. The appointments are to be made annually. The regents are empowered to fill vacancies and to make appointments on their own motion in case nominations are not made by the societies, and each examination conducted by a board must be under the supervision of an examiner appointed by the regents and not himself a member of either board. The regents are also to select the examination questions, which are to relate to anatomy, physiology and hygiene, chemistry, surgery, obstetrics, pathology and diagnosis, and therapeutics, "including practice and materia medica." The questions are to be the same for all the boards, except in therapeutics, in which they are required to be "in harmony with the tenets of the school selected by the candidate." The examinations are to be conducted in writing, and the regents are to license the successful candidates. After the date on which the act goes into effect, nobody can begin the practice of medicine in the State until he has received the regent's license. He has first to apply to the regents for the examination and license, paying a fee of $25 and furnishing satisfactory proof (by affidavit, if the regents require it) that he is more than twenty-one years old and of good moral character, has a medical diploma or license, and studied medicine three years, "including three courses of lectures in different years in some legally incorporated medical college or colleges" before the diploma or license was conferred upon him. The regents are authorized to accept licenses from other State boards maintaining an equal standard, together with a fee of $10.

We have lately received a number of inquiries as to these legislative provisions, and some of our correspondents have asked for our opinion as to their effects. As to certain matters of detail, it can hardly be said beforehand what the results will be. A great deal depends on the quality of the supervision exercised by the regents.

THE GERMAN SURGICAL SOCIETY.

A condensed report of the proceedings of the nineteenth congress of the German Surgical Society, held on the 9th, 10th, 11th, and 12th of April, has been issued in the form of a supplement to the *Centralblatt für Chirurgie* for June 21st. It makes a pamphlet of 104 large octavo pages, printed with the clearness and precision characteristic of the productions of Messrs. Breitkopf & Härtel. On the first page we find a table of contents in which the papers are classified under the heads of general pathology and therapeutics, the head and face, the vertebral column and the neck, the chest, the gastro-enteric canal and the liver, the urinary and sexual organs, and the limbs; and the papers are published in this order. It does not appear that the papers were read in an order corresponding to this classification, although that may have been the case, and such a procedure would have been quite in keeping with the regard for system usually displayed by our German colleagues. At all events, their systematic arrangement in the report and that of their titles in the table of contents must prove convenient to a reader seeking for a particular item in the proceedings, and it would have been an additional aid if the page numbers had been placed after the titles.

The report is to be commended not only for this judicious arrangement of the matter, but also for the admirable brevity with which the abstracts of papers and the substance of the remarks made in the discussions are given. The pith of about sixty papers and demonstrations is got into a little over a hundred pages, along with that of the discussions. It is particularly in the latter that condensation is shown; rarely does the summary of a discussion take up so much space as half a page. This shows either that the participants in the meeting were remarkably considerate or that the reporter was a master of his art: for we can not assume that anything of real importance was omitted or slighted, although it does look a little odd to see under the last heading (Demonstration of a Preparation of Congenital Sarcoma of the Dorsum of the Foot) only the terse statement "It was a small-celled spindle-cell sarcoma."

Among the names well known in this country we find the following in the report: Mikulicz, Bruns, Krause, Trendelenburg, Kraske, Rydygier, Riedel, Lauenstein, König, Ponfick, Madelung, Braun, Thiersch, Krönlein, and Helferich as those of authors of papers, and von Bergmann, Heidenhain, and Baumgärtner as those of participants in the discussions. Some of the noticeable titles were: The Proportion of Hæmoglobin in the Blood in Surgical Diseases, Actinomycosis, Ether and Chloroform Narcosis, The Treatment of Tubercular Affections with Iodoform Injections, Massage, Trephining, The Operative Surgery of the Vertebral Canal, Perityphlitis (three papers), The Radical Operation for Hernia, Operations for Intestinal Stenosis, Resection and Restoration of the Liver, Spiral Fractures, Neuropathic Diseases of the Bones and Joints, and The Treatment of Club-foot. Trendelenburg showed a remarkable operating-table, three woodcuts of which are given in the report. It is evident that the meeting brought out some of the best work of the best men in Germany, and that the society is one of great usefulness.

MINOR PARAGRAPHS.

THE REMUNERATION OF MEDICAL EXAMINERS IN LIFE INSURANCE.

It was an interesting discussion from more than one point of view that took place at a meeting of the Section in State Medicine of the Royal Academy of Medicine in Ireland, published in this issue. Many of our readers will probably be surprised to learn of the state of things mentioned by Sir William Stokes—namely, the payment of medical examiners in life insurance by fees proportionate to the amount of the policy to be taken by the applicant. It seems to us that the profession in Ireland ought not to fail in their efforts to have such an illogical system done away with. We are not aware that it has ever been in use in this country.

ANTISEPSIN.

In the *Lancet* for June 7th Dr. Cattani is quoted concerning the antipyretic properties of paramonobromacetanilide, or antisepsin. Its use in pneumonia with high temperature and in typhoid fever shows that its power to reduce body heat is equal to that of acetanilide. It likewise has antineuralgic properties. In the treatment of hæmorrhoids and other anal lesions its effects are marked when administered in the form of suppositories. As an antiseptic application to wounds and offensive ulcers, it has had some use with good results, the lesions generally healing quickly.

AN INTERESTING LITERARY REPRODUCTION.

A Newcastle-on-Tyne publishing firm, Messrs. Mawson, Swan, and Morgan, announce the fac-simile reproduction of an old manuscript volume entitled Y^e^ Apothecarie; his Booke of Recepts agaynst alle maner of sickenesses; allso howe to bake meates, to make Uskabaughe, to die clothe or woole, and divers usefull thinges besydes. The manuscript dates back about three centuries.

THE PUBLICATION OF PATIENTS' NAMES IN CLINICAL HISTORIES.

We have before pointed ont the impropriety of publishing patients' full names in the histories of their cases. There is seldom if ever any good reason for doing it, and it must often do violence to feelings that medical men are bound to respect. An esteemed correspondent has suggested to us to call attention to the matter again, and we do so with the feeling that it is one of no trifling importance.

COD-LIVER OIL AS A VERMIFUGE.

In a recent number of the *Union médicale* we find the following formula for an enema of cod-liver oil for the removal of the *Oxyuris vermicularis:* Cod-liver oil, 40 grammes (about 10 drachms); the yolk of an egg; water, 125 grammes (about 4 ounces). In case of failure, an enema of pure cod-liver oil is recommended.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 8, 1890:

DISEASES.	Week ending July 1.		Week ending July 8.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	11	5	8	0
Scarlet fever	34	10	43	2
Cerebro-spinal meningitis	1	0	2	2
Measles	276	25	271	23
Diphtheria	84	23	74	23
Varicella	1	0	4	0

The Chicago Gynæcological Society.—A meeting held on the 13th of June was devoted entirely to the memory of the late Dr. William H. Byford, who was one of the founders of the society. The programme included an address by Dr. H. P. Merriman and remarks by Dr. N. S. Davis, Dr. H. A. Johnson, and Dr. John E. Owens.

The Rush Medical College, of Chicago.—Dr. Henry M. Lyman has been appointed professor of the principles and practice of medicine, and Dr. James H. Etheridge professor of gynæcology.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, for the two weeks ending July 5, 1890:*

Suter, William N., First Lieutenant and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for two months, to take effect August 6, 1890. Par. 3, S. O. 149, A. G. O., June 26, 1890.

Borden, William C., Captain and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for three months and fifteen days, to take effect as soon as his services can be spared. Par. 11, S. O. 146, A. G. O., June 23, 1890.

Died.

Culbertson, Howard, Captain (retired), died June 18, 1890, at Zanesville, Ohio.

Appointments.

To be Assistant Surgeons, with the rank of First Lieutenant:

Keefer, Frank R., of Pennsylvania, June 6, 1890, *vice* Woodruff, promoted.

Raymond, Thomas U., of Indiana, June 6, 1890, *vice* Newton, resigned.

Snyder, Henry D., of Pennsylvania, June 6, 1890, *vice* Wilson, resigned.

Smith, Allen M., of New York, June 6, 1890, *vice* Matthews, promoted.

Heyl, Ashton B., of Pennsylvania, June 6, 1890, *vice* Hall, promoted.

Clarke, Joseph T., of New York, June 6, 1890, *vice* Porter, resigned.

Greenleaf, Charles R., Major and Surgeon, will, by direction of the Secretary of War, attend the encampment of the Pennsylvania National Guard at Mount Gretna, Pennsylvania, from the 18th to the 26th of July, 1890, for the purpose of accompanying the Surgeon-General of Pennsylvania in his inspection of the camp. Par. 11, S. O. 144, A. G. O., June 20, 1890.

Taylor, Marcus E., Captain and Assistant Surgeon. Leave of absence for one month, on surgeon's certificate of disability, is hereby granted, with permission to go beyond the limits of this Division, and to apply for an extension of five months. Par. 1, S. O. 45, Division of the Pacific, San Francisco, Cal., June 13, 1890.

Kimball, James P., Major and Surgeon. By direction of the Acting Secretary of War, leave of absence for four months is granted, to take effect when an officer of the Medical Department is assigned by his department commander to relieve him. Par. 6, S. O. 152, A. G. O., July 1, 1890, Washington, D. C.

Ball, Robert R., First Lieutenant and Assistant Surgeon, is relieved from duty at Fort Riley, Kansas, and will report in person to the commanding officer, Fort Spokane, Washington, for duty. Par. 7, S. O. 151, A. G. O., June 28, 1890, Washington, D. C.

Corbusier, William H., Captain and Assistant Surgeon, is relieved from duty at Fort Lewis, Colorado, and will report in person to the commanding officer, Fort Wayne, Michigan, for duty. Par. 7, S. O. 151, A. G. O., June 28, 1890, Washington, D. C.

By direction of the Secretary of War, the following-named Assistant Surgeons (recently appointed) will report in person for duty to the commanding officers of the posts designated opposite their respective names:

Keefer, Frank R., First Lieutenant, Fort Leavenworth, Kansas.
Raymond, Thomas U., First Lieutenant, Fort Sherman, Idaho.
Snyder, Henry D., First Lieutenant, Fort Reno, Indian Territory.
Smith, Allen M., First Lieutenant, Fort Snelling, Minnesota.
Heyl, Ashton B., First Lieutenant, Fort Niobrara, Nebraska.
Clarke, Joseph T., First Lieutenant, Fort Riley, Kansas.
Par. 6, S. O. 151, A. G. O., June 28, 1890, Washington, D. C.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending July 5, 1890:*

Page, J. E., Assistant Surgeon. Ordered to hospital, Mare Island, Cal.

Kennedy, R. M., Assistant Surgeon. Ordered to the League Island Navy Yard, Va.

Society Meetings for the Coming Week:

Tuesday, *July 15th:* Medical Society of the County of Otsego (annual—Cooperstown), N. Y.

Letters to the Editor.

NITROGLYCERIN IN GAS ASPHYXIA AND POISONING.

143 North Seventh Street, Zanesville, O., *July 7, 1890.*

To the Editor of the New York Medical Journal:

Sir: I see cases of gas poisoning successfully treated by nitroglycerin are being reported; therefore a few remarks relative to that subject will not be inappropriate. Since the publication of my article in your issue of December 14, 1889, I have received a letter from a personal friend, in which he spoke of a case that he had successfully treated with nitroglycerin subsequent to the publication of my article. It will be pertinent here to describe a case within my knowledge. One day last autumn, as I was passing along the street where several men were engaged in putting down new gas-pipes, I noticed a man lying inclined against a tree, apparently asleep, but whom I surmised to be asphyxiated by the escaping gas. He was receiving no attention whatever.

I examined him and found nothing except a shallow and irregular respiration to indicate that any condition other than that of natural sleep existed.

The superintendent of the gas company informed me that the man had been "gased," as he termed it, and had been carried aside to wait till noon, when a wagon would be brought to convey him to his home. The superintendent gave me the following information: This man was very susceptible to gas. During a period of fifteen years, which time he had been in the employ of this company, he had been asphyxiated some ten or twelve times. He usually remained unconscious for several hours—generally six or eight. This condition had become so familiar to his fellow-laborers and his family that its occurrence gave them no alarm. He retained the ability to swallow, and they were in the habit of giving him whisky. During some of his former asphyxiations he had had a physician, who, by the use of medicines and the battery, had failed to abridge the period of unconsciousness. They did not deem it necessary at this time to employ medical aid, and by the use of whisky he recovered in the usual time. He would no doubt have recovered as soon without the whisky, as I could see no indication for it.

It seems to me there should be a division of these cases into those of asphyxia and those of real poisoning. In asphyxia, recovery is rapid. In poisoning, the poison has a firm hold on the system and is not eliminated for several hours. Whether there is any pathological difference or not except in degree I do not know, but the fact that one person will recover in an hour or two, while another with the same treatment will remain comatose for twenty-two hours, I think is sufficient to justify the distinctions mentioned. To substantiate my claim of originality in the treatment, I have simply to say that I used it for the first time in gas poisoning on November 20, 1888—almost a year before it was used by any one else, so far as reported.

I did not report my case sooner because I had been using nitroglycerin as a stimulant some time before I treated my case, and was not aware that it had any other property than that of a stimulant, nor do I now know its *modus operandi* if it is other than by stimulation.

J. C. Crossland, M. D.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of June 5, 1890.

The President, Dr. A. L. Loomis, in the Chair.

Bacteriological Researches in Yellow Fever.—In a paper with this title, Dr. G. M. Sternberg, of the United States Army, said that in 1879 he, as a member of the Yellow-Fever Commission sent to Havana by the National Board of Health, had devoted himself especially to a search for the specific infectious agent in the blood of patients in various stages of yellow fever. The result of this research had been negative. Extended researches made during the past two years by the most approved bacteriological methods had fully confirmed this negative result. Exceptionally micro-organisms were found in cultivations from the blood and tissues, even when the autopsy was made very soon after death, but the bacillus encountered most frequently had been identified as the *Bacterium coli commune* of Escherich, which was constantly present in the intestine of healthy persons, and consequently could not be the specific pathogenic agent in yellow fever. Other micro-organisms associated with this were found so exceptionally and in such small numbers that no special significance could be attached to their presence. The examination of thin sections of the liver, kidney, and other organs, stained by the most approved methods for demonstrating micro-organisms, gave results corresponding with those obtained by cultivation methods.

That various micro-organisms were present in small numbers

in the liver and kidney (and presumably in other organs) at the time of death was shown by preserving fragments of considerable size in an antiseptic wrapping which destroyed all micro-organisms which might have accidentally fallen upon the surface of the fragment and prevented the entrance of germs from without. Such a fragment preserved for forty-eight hours at a temperature of 27° C. (80·6° F.) always contained a large number of bacilli of different species which had evidently developed from scattered bacilli present in the organ from which it was taken at the autopsy. These bacilli were for the most part anaerobics, or facultative anaerobics, and did not give rise to a putrefactive odor. The tissue containing them had a very acid reaction. Putrefactive organisms were also present, and pieces of tissue kept for a longer time gave evidence of putrefactive decomposition.

The micro-organisms present in fragments of liver and kidney preserved in the way indicated had been carefully studied, and numerous comparative researches had been made, since his return from Havana, which showed that those most constantly and abundantly present were not peculiar to yellow fever. In cases of accidental death and of death from other diseases fragments of liver preserved in the same way had contained the same micro-organisms. His bacillus *n*—a large anaerobic bacillus, which for a time he had thought might be the specific germ he had been in search of—he had found in these comparative researches, and been obliged to exclude it from further consideration from an ætiological point of view. One bacillus, however, which was found in a considerable number of cases of yellow fever, in pieces of liver preserved in an antiseptic wrapping, although not in very great numbers, had not been found in his comparative autopsies. This was a non-liquefying bacillus which resembled the colon bacillus in its growth in flesh-peptone-gelatin and in its morphology, although it was somewhat larger. It was also more pathogenic, especially for rabbits. This was his bacillus *x*. Not having excluded it by his comparative researches, he looked upon it as being possibly the specific yellow-fever germ, but he had not been able as yet to obtain any satisfactory experimental evidence that such was the case. This same bacillus was found in the contents of the intestine where it was associated with a variety of other bacilli, some of which were strict anaerobics and some facultative anaerobics. The most constant and abundant of these was the *Bacterium coli commune* of Escherich.

Comparatively few liquefying bacilli were found in the contents of the intestine or stomach, or in cultivations from pieces of liver and kidney preserved for forty-eight hours in an antiseptic wrapping. The bacillus of Dr. Paul Gibier had been found in the contents of the intestine in a limited number of cases, but it had been absent in a majority of the cases in which the speaker had made autopsies—forty-three in all—and, when present, had not been abundant as compared with the non-liquefying bacilli. And it was not found in any considerable number of cases in his cultivations from fæces collected during the lifetime of the patient. There was therefore no good reason for supposing that this bacillus had anything to do with the ætiology of yellow fever. And, as a result of his extended cultivation experiments, he felt justified in asserting that yellow fever was not due to a liquefying aerobic micro-organism.

The micrococcus which Dr. Domingos Freire had presented to him as his yellow-fever germ at the time of the speaker's visit to Brazil grew readily in flesh-peptone gelatin, and caused liquefaction of this medium. Its presence would therefore be readily ascertained by the culture methods which he had employed. It had not been present in a single instance in his cultivations from the blood and tissues or from the contents of the intestine. It was therefore excluded from consideration as being concerned in the ætiology of yellow fever. The *Tetragenus febris flavæ* of Dr. Carlos Finlay, of Havana, was a common atmospheric organism in that city which the speaker had obtained in cultivations from the surface of the body of patients suffering from various diseases, and of healthy persons. He had not obtained it in his cultivations from the blood and tissues, and considered it definitely excluded as the possible ætiological agent in the disease under consideration.

The morphological characters and mode of growth in various culture media of the different micro-organisms referred to, and of others encountered in his bacteriological researches, would be demonstrated by projecting upon a screen his micro-photographs and photographs of colonies and test-tube cultures. A detailed report containing a full account of the researches made during the past two years in Havana, Cuba, and Decatur, Alabama (1888), was now nearly completed, and would be submitted to the President within a short time.

The PRESIDENT, in closing the meeting, said that this was the last meeting in the old building. It was now about twenty years since it became the property of the Academy, during which time the membership had more than doubled; the library had been increased more than two thousand volumes; eight sections in the different departments of medicine and surgery had been organized and were doing efficient work. Here had been fought and settled many scientific and ethical questions. Clouds had darkened the skies, but they had been dispelled by the intelligence and wise councils of the fellowship of the Academy. This building was left with a united, enthusiastic fellowship which numbered nearly seven hundred. As the Academy entered its new building, let it be with the resolve that it should be a place for better scientific work, and where should be cultivated more largely the social side of our professional life.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION IN STATE MEDICINE.

The President, Dr. A. W. FOOT, in the Chair.

Meeting of Friday, February 7, 1890.

The Medical Selection of Lives for Assurance.—Instead of the usual introductory address, the president of the Section read a paper on this subject. The responsible and often difficult duties of a medical examiner were very different from those of an ordinary practitioner. The questions set forth in the proposal sheet were regarded by some as vexatiously minute and unnecessarily numerous; but the reader anticipated that ere long the companies would require information as to the condition of the retina, the state of arterial tension, the integrity of the various reflexes, the centesimal excretion of urea, the nutrition of nerves and muscles as estimated by electricity, microscopic details of urinary sediments, and a statement of the respiratory capacity. Referring to the proposal forms, he criticised the tenacity with which companies clung to the ideal configuration of an apoplectic person, as short, stout, thick, and red. He maintained that there were no external indications of the arterial degeneration which was the proximate cause of cerebral hæmorrhage. Meanwhile there was little, if any, attention paid to the significance of aural discharges, to that of recurrent erysipelas (especially facial), to that of latent disease of the rectum, and to cases of fæcal obstruction. The embarrassments which the conscientious discharge of an examiner's duty might involve were illustrated, and the severance of life-long friendships in consequence was cited. Several points of a practical nature were made in reference to consumptive lives, and the means adopted to blind examiners. The important subject of "habits" with refereuce to the use of alcohol was fully treated

of. The question of the acceptance of an albuminuric life was discussed, and the rejection of it under any circumstances recommended. In like manner, persons with chronic mitral regurgitation were considered unsound from an assurance point of view, though in private practice they might, with care and attention, live long and efficiently.

Professor Purser said that the medical man should state, in the clearest language, what he believed to be the condition of the applicant's health, and it was for the company then to settle whether they would reject him altogether or take him with an addition, to be determined with the aid of an actuary. It was difficult to know what value to put on family history. Often it was difficult to say what a patient died of; and, again, post-mortem examinations disclosed that the causes were different from what the doctor thought. He did not think that the Registrar-General's returns were sufficiently accurate to found scientific conclusions upon them. As regarded renal disease, if he found an applicant had albuminuria he advised that the case should be postponed for three or six months, or a year; and if there was albumin in the urine when he came up again he was rejected, but if not he was accepted. No matter how long a person might live who had albuminuria, he did not think such an applicant safe to accept on any terms. For a considerable period of his experience in examining during the past twenty years it had been left optional by the company to examine the urine for albumin, and his practice, accordingly, had been to examine it only where he had reason to suspect there was something the matter with the kidneys; but for some years past he had been obliged to examine for sugar and albumin in every case, and in a considerable proportion of the applicants, in whom there was no reason to suspect anything the matter with their kidneys, he had found albumin, and, though apparently in perfect health, they were rejected.

Dr. McSwiney said that, though he was not an examiner for an insurance office, cases had come under his observation upon reference, as an independent physician, on the question of suitability for assurance. He asked what effect the opium habit ought to have in determining the question. Having regard to the advances in surgical science, he also asked whether hernia, which was now so successfully cured by the radical method, would involve rejection; and also as to the conclusion to be drawn from the presence of hæmorrhoids, which might be regarded as symptomatic of other disease. Organic valvular disease was another point upon which he desired a definite opinion.

Dr. Bewley, as an examiner for an insurance company, said that he had met with two cases of primary syphilis followed by eruptions. He submitted that an applicant so suffering ought not to be considered on a par with a man who never had had syphilis.

Dr. E. MacDowel Cosgrave said insurance offices were now, as a rule, alive to the importance of the symptom of albumin in the urine; so that, at any rate in all cases of policies for over £500, the compulsory examination of the urine was the rule. One company, with which he was himself connected, had solved the difficulty in dealing with slight deviations from health in a peculiar and satisfactory way. Instead of loading the premiums, a policy was issued at the ordinary rates, but the amount of the policy was payable on a sliding scale. Thus, where the amount was £1,000 and the expectation of life twenty-five years, if healthy, the policy was issued upon the terms that if the insured died in the first year the liability of the company would be only £800; but each year of life increased the policy, so that in twenty-five years the policy was for £1,000. Thus there was no "loading" for lives which lived the full expectation. The plan seemed to work well, and lessened the difficulties of the examiner.

Sir William Stokes said there were some practical difficulties in the way of carrying out some of Dr. Foot's suggestions—for instance, in the case of females, however theoretically desirable an examination of the rectum might be, it was impracticable. Nothing could be more pernicious and unfair than making the doctor's fee for examination proportionate to the amount of money insured; because the medical man who discharged his duty must necessarily have the same trouble in examining a person seeking to insure for only £100 as in the case of a person insuring for £10,000; and he thought the medical profession ought to make a stand on the point. His experience did not coincide with Professor Purser's in meeting persons who told the truth as regarded their habits of life, especially persons of intemperate habits. He had known three cases of intemperate or free drinkers who had exercised self-denial for months, and had then gone before a doctor and denied that they were, or had been, of intemperate habits, and so passed as first-class lives; but immediately afterward reverted to their old habits, got ill, and died. Notwithstanding the advances in surgery, he would not recommend a person with hernia as a first-class life; he would be extremely apprehensive of the result of the operation for the radical cure. Even after a successful operation the hernia might come back again, perhaps in a form more difficult to deal with than before. Neither would he accept a person afflicted with hæmorrhoids as a first-class life. The operation only dealt with the existing condition of the parts the seat of the disease, and not with the conditions which brought about the disease. He would not recommend cases of albuminuria to be taken under any circumstances, the presence of albumin being sufficient indication of "something rotten in the state of Denmark" in connection with the kidneys.

Dr. Donnelly, Dr. W. Stoker, Dr. F. Nixon, and Sir C. Cameron having made some remarks, Dr. Foot replied. He concurred with Professor Purser as to the duty of a medical man to regard the interests of his company as paramount. He rejected albuminurics and risky lives, acting on the principle that it was better to have a few good sound lives whose premiums were sure for years than to pass lives at high premiums which might be lost at any time. It was difficult in some cases to give a decisive opinion "yes" or "no" in answer to the question whether a particular life was a good one or not, so many circumstances had to be considered and weighed; but the company required that he should come to a definite conclusion without setting out his reasons. It was important to ascertain about scarlatina and infantile diseases; for instance, scarlatina was less likely to lead to renal complications in a child than in an adult. As regarded the opium habit or morphinism, the point had been settled in the case of the Earl of Mar, that it did not shorten life. Hernia cases were suspicious, though a great many people wore trusses without need of them. Hæmorrhoids always suggested an examination of the rectum, for cancer of the rectum had often been called piles. He was against passing cases of organic disease of the heart. Syphilis was an unfavorable condition; but it was a matter of judgment how far the life might be shortened, and in such cases a consultation would be desirable. He concurred as to the absurdly small fees for examining cases for policies of small amount. As regarded females, as a rule men insured for women, not women for men; but there were ways of examining the urine or the rectum, and if there was a question of fissure or piles, an examination should be made. He was not so trustful as Professor Purser, and he believed that alcoholism and morphinism were habits deteriorating the organ of truth. Tobacco, taken in large quantities, especially the coarse, common tobacco, handicapped the nervous system.

Book Notices.

A Guide to the Diseases of Children. By James Frederic Goodhart, M. D., F. R. C. P., Physician to Guy's Hospital and Lecturer on Pathology in its Medical School, etc. Rearranged, revised, and edited by Louis Starr, M. D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania. Second American from the Third English Edition, with Numerous Formulæ and Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. 13 to 772.

The English editions of this work made many friends. In a new dress it can scarcely be less welcome, though much less convenient and pleasant to study. The chapters on general non-infectious diseases are of particular interest, as well as the author's views of nervous disorder during childhood. Skin disease receives little more than passing mention, the ground being so well covered throughout the extensive literature of the subject. The dietetics of childhood is considered in every department, and constitutes, as elsewhere, one of the most important elements of hygiene. The book is the record of careful observations and well-weighed conclusions.

Psychology as a Natural Science applied to the Solution of Occult Psychic Phenomena. By C. G. Raue, M. D. Philadelphia: Porter & Coates, 1889. Pp. 8–9 to 541.

This exposition of psychology has evidently been undertaken with much earnestness of purpose. In parts it is suggestive, with sentences here and there capable of serving as texts for the sermons of other writers on psychology. At the same time the line of argument is old, very old, and not in touch with the spirit of modern investigation. It is impossible to see wherein the book can be of any particular value to the nineteenth-century doctor, whose aim is to study the orderly arrangement of facts according to an underlying principle.

The Cure of Crooked and Otherwise Deformed Noses. By John B. Roberts, A. M., M. D., Professor of Anatomy and Surgery in the Philadelphia Polyclinic. Philadelphia: P. Blakiston, Son, & Co., 1889. Pp. 7 to 24.

In many cases the disfigurement caused by a deformed nose is the cause of more distress to the patient than a more serious but concealed defect might be, and he has a right to expect from the surgeon the best efforts consistent with safety to relieve this mental distress. To the surgeon, then, who will determine to relieve this form of suffering to the best of his ability we commend this little monograph, which contains the results culled by the author from his experience.

Clinical Lectures on Varicose Veins of the Lower Extremities. By William H. Bennett, F. R. C. S., Surgeon to St. George's Hospital, etc. With Three Plates. London: Longmans, Green, & Co., 1889. Pp. ix to 93.

It is only too frequently the case that much labor is devoted to the study of rare forms of disease, while little attention is paid to the common forms, because they are usually considered uninteresting. Still, it is his success or failure in the latter which, as a rule, makes or mars a physician's reputation, and Mr. Bennett has proved in this book that careful study of ordinary cases will make them interesting and bring to light new features in their diagnosis and treatment. The work presents the most thorough consideration of the subject of varicose veins that we have met with, and is particularly valuable regarding the diagnosis of the incipient stage and the various forms of treatment. It is divided into four lectures, the first devoted mainly to the causes and complications of varicose veins; the second, to the incipient stage and to varix at the saphenous opening; the third, to non-operative treatment; and the last to operative treatment. It is essentially practical and strongly commends itself, especially to the general practitioner.

Études de clinique infantile. Syphilis héréditaire précoce; laryngite syphilitique; broncho-pneumonie par infection intestinale; prophylaxie de la rougéole et de la diphthérie à l'Hospice des enfants-assistés. Par le Dr. Sevestre, médecin de l'Hospice des enfants-assistés. Paris: E. Lecrosnier et Babé, 1889. Pp. 3 to 141. [Publications du *Progrès médical.*]

This work consists of four monographs. That on hereditary syphilis is devoted chiefly to symptomatology, and fairly presents our present knowledge upon that subject. That upon the laryngeal manifestations of the disease in infants is of special interest, as it treats in detail of a subject upon which very little has been written.

Several cases of diarrhœa with consecutive pneumonia are interesting, but are capable of an entirely different interpretation from that put upon them by the author. The proposition that pulmonary congestion and broncho-pneumonia may result from infection due to decomposition of the contents of the intestine in fœtid diarrhœa requires much more evidence for its proof than the author adduces.

Perfect isolation as the chief prophylactic measure in measles and diphtheria the author has found most satisfactory.

The Pharmacopœia of the London Skin Hospital. Edited by James Startin, Senior Surgeon to the Hospital. London: Harrison & Sons. Pp. 23.

This little book is doubtless useful to the attendants at the London Skin Hospital. It contains a few of the formulæ to be found in all the recent text-books; some good, some poor. There is, or should be, little popular demand for books of this class, excellent as they may be in themselves and for the purpose for which they were primarily compiled.

Transactions of the American Association of Obstetricians and Gynæcologists. Vol. II. For the Year 1889. Philadelphia: W. J. Dornan, 1889. Pp. xxxviii–397.

The second meeting of this association was fully equal to the former one in point of interest and enthusiasm. The predominant subject of the volume is abdominal surgery; in fact, it overshadows all the others. One finds many positive statements in the discussions of this subject, sometimes defended with great ardor. It is well to have convictions, but it is also well to remember that there are few methods of practice in abdominal or any other department of surgery which are insusceptible of change or improvement. In other words, abdominal surgery is not completed. Equally good results are obtained by those who base their practice upon antisepsis and by those who do not. There are those who make a good argument against the necessity of the over-careful toilet of the peritonæum, the necessity or the efficiency of its irrigation with hot water, and the harmfulness of blood-serum or blood-clot in moderate quantities; and these are matters which have been deemed fundamental by most of the disputants in the discussions under consideration.

Spinal Concussion: surgically considered as a Cause of Spinal Injury, and neurologically restricted to a Certain Symptom Group, for which is suggested the Designation Erichsen's Disease, as one Form of the Traumatic Neuroses. By S. V. Clevenger, M. D., Consulting Physician, Reese and Alexian Hospitals; late Pathologist, County Insane Asylum, Chicago, etc. With Thirty Wood Engravings. Philadelphia and London: F. A. Davis, 1889. Pp. v–359. [Price, $2.50.]

This book purports to be on spinal concussion, a subject which deserves careful, conscientious observation on the part of an author, combined with persistent study of the observations of others. In other words, the ideas and observations of various writers should be concisely and critically arranged together with the author's own experience, so as to make the work a unit. It is to be regretted that this has not been done in the present work. The larger part is devoted to translations and quotations from various writers, with some additions by the author, but with little attempt at unification It is little more than an imperfect collection of writings on the subject. An entire chapter is given to the subject of electro-diagnosis, and most of it might have been omitted with propriety. A bitter attack upon the scientific and medical institutions of the country is not likely to prove conducive to the popularity of the book, and the interjection of references to private differences with the local authorities does not appear to be in good taste. Still, if the work furnished any real advance in the study of this important subject, these faults, as well as the boastful style, might be overlooked. The book is well got up typographically and the cuts are excellent.

The Clinical Use of Prisms; and the Decentering of Lenses. By Ernest E. Maddox, M. D., late Syme Surgical Fellow, Edinburgh. Bristol: John Wright & Co., 1889. Pp. iv–7 to 113.

This little book is written from a practical point of view, and is intended to be an aid to precision in the use of prisms rather than a demonstration of the author's mathematical talent. While it is worthy of the perusal of those skilled in this branch of ophthalmology, it is adapted to the needs of practitioners who, though not so skilled, dabble in this form of practice. A *résumé* of the writings of Dr. Stevens on this subject is given in the appendix.

BOOKS AND PAMPHLETS RECEIVED.

Intestinal Anastomotic Operations with Segmented Rubber Rings, with some Practical Suggestions as to their Use in other Surgical Operations. By A. V. L. Brokaw, M. D., St. Louis, Mo. [Reprinted from the *Transactions of the Southern Surgical and Gynæcological Association.*]

New Methods of performing Pylorectomy, with Remarks upon Intestinal Anastomotic Operations. By A. V. L. Brokaw, M. D., St. Louis, Mo. [Reprinted from the *St. Louis Courier of Medicine.*]

Some Points on the Perinæum and Forceps, with a Description of a New Method of assisting the Perinæum, and a New Combined Axis Traction Forceps to be used as an Alternative for Craniotomy. By T. J. McGillicuddy, M. D. [Reprinted from the *American Journal of Obstetrics and Diseases of Women and Children.*]

Two Cases of Resection of the Cæcum for Carcinoma, with Remarks on Intestinal Anastomosis in the Ileo-cæcal Region. By N. Senn, M. D., Ph. D., Milwaukee. [Reprinted from the *Journal of the American Medical Association.*]

L'intoxication chronique par la morphine et ses diverses formes. Par le Dr. L. R. Regnier, ancien interne en médecine des hôpitaux de Paris. Paris: E. Lecrosnier et Babé, 1890. Pp. 5 to 171. [Publications du *Progrès médical.*]

The Condition of the Blood in Chlorosis. Notes on the Course and Secondary Symptoms of Chlorosis. By Charles N. Dowd, M. D. [Reprinted from the *American Journal of the Medical Sciences.*]

Du rôle physiologique et thérapeutique de l'azote gazeux, considéré principalement dans les eaux minérales des Pyrénées. Par le Docteur E. Duhourcan. [Extrait de la *Revue des Pyrénées et de la France méridionale.*]

Uric-Acid Diathesis in Affections of the Eye, Ear, Throat, and Nose. By W. Cheatham, M. D., Louisville, Ky. [Reprinted from the *American Practitioner and News.*]

Reciprocal Responsibilities. An Address delivered on the part of the Faculty at the Forty-first Commencement Exercises of the Medical Department of Georgetown University, at Lincoln Hall, on May 5, 1890. By Swan M. Burnett, M. D., Ph. D., Washington.

Climatology and Diseases of Southern California. By F. D. Bullard, A. M., M. D. [Reprinted from the *Southern California Practitioner.*]

Les bactéries et leur rôle dans l'étiologie, l'anatomie et l'histologie pathologiques des maladies infectieuses. Par A. V. Cornil, Professeur d'anatomie pathologique à la Faculté de médecine de Paris, et V. Babes, Professeur à la Faculté de médecine, etc. Troisième édition, refondue et augmentée, contenant les méthodes spéciales de la bactériologie. 385 figures en noir et en plusieurs couleurs intercalées dans le texte et 12 planches hors texte. Tome Premier. Pp. vii–582. Tome Second. Pp. 608. Paris: Félix Alcan, 1890. [Prix, 40f.]

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.

Enophthalmia Traumatica.—Gessner (*Arch. of Ophthal.*, xviii, 3) reports three cases of this peculiar result of external injury, and adds some remarks on the genesis and disturbance of mobility connected with enophthalmia. These cases were all observed by Nieden, who excluded the presence of microphthalmia on account of the equality of the cornea, refraction and acuteness of sight in both eyes. Nieden thought that the enophthalmia was due to atrophy of the retro-bulbar tissue, owing to strong and prolonged compression. Gessner, on the contrary, regards the orbital injury as the cause of the enophthalmia. Contused wounds of the orbital margin usually involve the periosteum and bone, and the subsequent inflammatory reaction is readily propagated to the orbital cellular tissue. He thinks that the enophthalmia is produced by the mechanical falling back of the globe into the orbital cavity, the contents of which have been reduced by cicatricial contraction of the retro-bulbar cellular tissue; and this may be aided by a certain pressure of the lids. An inflammatory participation of the ocular muscles is improbable, on account of the absence of disturbance of motility.

Two Cases of Detachment of the Chorioid after Cataract Extraction; Spontaneous Recovery.—Groenouw (*Arch. of Ophthal.*, xviii, 3) reports two cases of this disease because of the extreme rarity of chorioidal displacement. The detachment simulated very strongly the appearances of chorioidal tumor. They were probably hæmorrhagic extravasations excited by the extraction, and lying between the chorioid and sclera, bulging forward the retina and chorioid, and simulating a tumor. There was not even a simple detachment of the retina without a simultaneous detachment of the chorioid; the immobility of the tumor, the absence of varicose vessels and of any elevation or fold upon the surface, and, above all, the shimmering chorioidal pigment, necessarily pointed to a detachment of the chorioid. The cause of the detachment is to be sought in the vacuum following the sudden extraction of the lens, though probably some pre-existing disease of the chorioid is also necessary. The diagnosis between tumor and detachment of the chorioid can only be accurately made by following the case for some time.

Non-metallic Foreign Bodies in the Cornea.—Ritter (*Arch. of Ophthal.*, xviii, 3) here discusses the subject of the presence of animal

and vegetable particles lodged in the cornea, and the mutual action of the foreign body and the epithelium upon each other. His first examination revealed the presence of micro-organisms. The *root bacillus* was very frequently found, and its growth, like a nerve-plexus, is so characteristic that it can not be mistaken. The *hay bacillus* is also frequent on foreign bodies in the cornea; it is as long as the root bacillus, but finer, and forms long, jointed fibers, growing in gray, round colonies, and rapidly liquefying the gelatin. Two other corneal micrococci greatly resemble the hay bacillus; one, the diplococcus cinerareus corneæ, grows rapidly, and soon liquefies the gelatin. The second, coccus cinerarens corneæ, is single, with gray, roundish colonies quickly liquefying. A large number of micro-organisms, which occur in the soil and in the air and water, also flourish on foreign bodies in the cornea. They are to be regarded here as saprophytes, and have either attained the cornea with the foreign body, or else in some manner reached the conjunctival secretion and thence remained clinging to the foreign body. They live here upon and in the corneal epithelium, and their final action is to loosen the foreign body from its seat.

Peculiar Course of a Retinal Glioma.—Hosch (*Arch. of Ophthal.*, xviii, 3) reports an interesting case occurring in a boy, aged three years and a half, whom he first saw in September, 1885. Both eyes were involved by the disease, and enucleation was therefore not advised. Six months later the child was reduced to the condition of a skeleton. The right eye protruded far forward, the cornea was opaque, and the conjunctiva red and chemotic. The sight of the left eye seemed fairly good, and the ophthalmoscopic appearances of the disease were about the same as at the first examination. The child died a month later, and both eyes were enucleated and subjected to examination, and the results are here given. The relatively slight extension of the glioma in the left eye explains the prolonged preservation of sight. The neoplasm extending from the retina into the papilla, and excavating it deeply, had evidently pushed the nerve fibers to one side, without destroying them, so that the peripheral portions of the retina still preserved some perception of objects. It was an interesting fact to observe that the tumor encroached upon the optic nerve and yet spared the retina and vitreous. The extensive proliferation of pigment here met with sharply defined the limits of the neoplasm and extended far behind the excavation into the papilla. The course of the disease in the left eye varied greatly from the common run of cases. While the disease progressed as usual in the right eye, the pathological process in the left eye clung to the neighborhood of the posterior pole without affecting the entire retina early in the disease, and detaching it from the chorioid, as almost invariably happens. It is scarcely possible that the tumor can have crossed over from the right eye through the chiasm, for the gliomatous elements would then have increased as the brain was approached, which was not the case. It must, therefore, be concluded that the disease affected both eyes, running the usual course in the right eye, while in the left it remained localized around the papilla, and then very slowly extended into the optic nerve.

Unequal Accommodation in Healthy Eyes and in Anisometropia.—Fick (*Arch. of Ophthal.*, xviii, 3) concludes from his observations that the axiom, that unsymmetrical accommodation is impossible, is false, and must be erased from the text-books on ophthalmology. Into its place steps the fact that, even under physiological conditions, the accommodation of one eye can act independently of that of the other; independent, however, only within certain limits. This unequal accommodation can only be obtained by a perceptible and sometimes a painful exertion, and the eyes only bring it into use in so far as it is indispensably necessary in the interest of the act of vision. In fitting anisometropes with glasses, three points should be considered: 1. The breadth of accommodation in both eyes singly. 2. The variation of accommodation in one eye when that of the other remains, as far as possible, unchanged. 3. The alterations of refraction needed for the least trying combined binocular reading. Fick believes that meridional asymmetrical accommodation is possible, and that the asthenopia of many astigmatics is caused by the effort to compensate for the corneal astigmatism by meridional asymmetrical accommodation.

The Cause of Senile Cataract.—Schoen (*Arch. of Ophthal.*, xviii, 3) draws the following conclusions from his investigations: 1. The process heretofore distinguished as senile cataract begins always as equatorial cataract, with fine white dots or streaks (never with clefts). 2. Nuclear sclerosis never appears without equatorial cataract. On the other hand, the statistics show three hundred and seventy-seven eyes with equatorial cataract without nuclear sclerosis. The latter is without doubt secondary. 3. Nuclear sclerosis is associated with equatorial cataract first after the age of sixty. 4. More than half (sixty per cent.) of the patients with cataract have still normal acuteness of vision, wherefore changes in the center of the lens may be excluded. 5. Anterior cortical cataract is rarely associated with equatorial cataract before the age of fifty. 6. Cataracta simplex is not peculiar to old age, but frequently occurs in its incipiency in young people from twenty to thirty years of age. The designation "senile" should therefore be dropped, and "simplex" employed in its place. 7. Three fourths of the total number of cataractous eyes are hypermetropic or astigmatic. 8. Equatorial cataract begins chiefly in the horizontal meridian. 9. The macroscopic dots and stripes correspond to the insertion of the anterior and middle zonular fibers. 10. The microscopical changes likewise are arranged around the base of these fibers.

The Degeneration of the Center of the Retina in Old People.—Hirschberg (*Ctrlbl. f. prakt. Aug.*, September, 1889) states that, when healthy people of an advauced age lose their acuteness of vision for fine objects, so that they either can not read at all or do so with great difficulty, while they still possess excellent eccentric vision and find their way about without difficulty, there will be found at the center of the fundus in both eyes small, circumscribed, bright spots of discoloration, and in some of these small crystals may be seen. The visual tests show diminution of the central acuity of vision to $\frac{1}{12}$ and even less, and a defect in the center of the visual field. The process is slowly progressive and the vision steadily diminishes. In the center of the retina are seen rose-colored spots, in which are white spots with crystals; and in the vicinity are recent, grayish-blue spots behind the vessels. At the periphery there are black spots. The change is not limited to the retinal center. Treatment is futile, but the disease does not proceed to blindness.

A Case of Detachment of the Retina treated by Schoeler's Injection Method, with Fatal Result.—Gelpke (*Ctrlbl. f. prakt. Aug.*, September, 1889) reports a distressing case of this kind occurring in a robust elderly man of sixty-six years. The detachment had occurred in a hitherto perfectly healthy eye without any known cause. Three drops of tincture of iodine were injected into the vitreous according to Schöler's method, all the steps before, duriug, and after the operation being carried on under the most rigid antiseptic rules. In spite of everything, an infectious purulent chorioiditis was set up in the eye, and two days later this was followed by a purulent meningitis, which caused the patient's death on the sixth day.

The Treatment of Detachment of the Retina.—Ulrich (*Kl. Mon. f. Aug.*, September, 1889) gives in detail his method of treating cases of detached retina. The first condition of a successful treatment in the first stage is rest in bed and the use of salicylate of sodium as an absorbent. In addition to this comes the pressure bandage whenever it can be borne. It should not be removed except when the patient is in bed. The salicylate of sodium should be given in sixteen-grain doses (one gramme) every hour for four or five hours, and every third day it should be omitted for a day. After the first month of this continuous treatment, the treatment is modified in such manner that the patient passes one week in every month in bed, and during this period he takes six times five grammes of salicylate of sodium. In the interval moderate exercise may be allowed.

Extirpation of the Lacrymal Gland causing Atrophy of the Optic Nerve through Hæmorrhage into the Orbit.—Gifford (*Amer. Jour. of Ophth.*, September, 1889) reports a case of this nature in a man aged sixty. History of dacryocystitis on left side for a year, with moderate stricture of the lacrymal canal and ectropium of lower lid. The upper canaliculus was slit and the usual probing aud syringing treatment carried on for ten days with improvement. Then a stationary period began and lasted for several days, and it was decided to extirpate the lacrymal gland, which was done under ordinary antiseptic precautions. The incision, an inch long, was made just below the eyebrow at the outer side, and was inclosed with an interrupted suture. There was an

unusually free hæmorrhage during the operation, and the bandage had to be changed twice in thirty hours, on account of oozing from the wound. When the dressing was changed the second time, the oozing had ceased, but the upper lid was so infiltrated with blood that the eyelids could not be opened. The wound healed without a trace of reaction, but the upper lid and conjunctiva were full of coagulated blood, the skin was of a purple hue, and the patient complained of a dull pain in and around the orbit. Four weeks later there was complete left ptosis, the left eye was completely motionless, the pupil was moderately dilated, the direct light reflex was absent, the media were clear, the retina was filled with hæmorrhages, not fresh, but old and partially absorbed. The vessels were small and the optic papilla was completely white. No record is made of the testing of the vision, but in the history the man states that the eye was blind.

The Restoration of the Eyelids and the Disadvantages of Cutaneous Grafts.—Valude (*Arch. d'ophthal.*, July–August, 1889) thinks that the disadvantages of blepharoplasty by means of a facial flap are as follows: 1. It may leave a second deformity much more considerable than the first if union does not take place, and especially if the flap becomes gangrenous. 2. It can not succeed if the neighboring parts consist of cicatricial tissue of feeble vitality. 3. It produces in the face seams and cutaneous folds which are shocking additional deformities. On the other hand, the advantages of this form of blepharoplasty may be stated as follows: 1. Even if the result of the operation is a failure, the consequent inconvenience is almost *nil*. No tissue is lost, and any other operation may be essayed. 2. The cutaneous graft may always be procured with the same facility. 3. No new deformity is added to the physiognomy. Valude thus voices the general opinion of the Paris Surgical Society in regard to skin grafts: 1. When the cicatricial skin is thin, elastic, shining, very dry, slightly vascular, entirely fibrous, adherent to the subcutaneous layers, or separated from them by a loose cellular tissue, skin grafting should not be attempted. 2. If, on the contrary, the cicatrix only involves the superficial layers of a thick skin, if it is furnished with a well-nourished panniculus adiposus, without adhesions to underlying parts, the skin grafting is indicated. 3. Even when the anatomical conditions are not very favorable, the cicatricial tissue may be utilized for grafts, though they must be very small. 4. Cicatricial tissue may unite by first intention with analogous tissue and with healthy tissues. 5. Cicatricial flaps are exempt from several inconvenient accidents which frequently involve those taken from healthy parts; they lie flat, do not rise above the surrounding parts, and do not swell and form nodules, as healthy skin grafts often do. 6. When the face has been greatly disfigured by a scar, and only part of it, as the eyelids, is to be repaired, it is better to employ a cicatricial graft.

The Heredity of Myopia.—Motais (*Arch. d'ophthal.*, July–August, 1889), from an examination of all the members of 330 families of young myopes, draws the following conclusions:

1. The hereditary influence of myopia is manifest.

2. It existed in 216 families out of 330, or 65 per cent.

3. Hereditary myopia is distinguished from acquired myopia by its early appearance, its rapid development, and by frequent and serious complications.

4. Myopia is usually transmitted from father to daughter (86 per cent.) and from mother to son (79 per cent.); hence hereditary myopia is crossed from the sexual standpoint.

5. The principal conditions which favor the hereditary transmission of myopia are: 1. The use of the eyes in an unfavorable hygienic environment either at school or at home. 2. Astigmatism of a certain degree (above D. 0·75), 14 per cent. 3. Microsemia or lowering of the orbital arch, 30 per cent.

6. The deduction of the exact demonstration of hereditary myopia to a great extent (65 per cent.), and of the serious nature of the affection, should be carefully impressed upon all who are engaged in the education of children.

The Extirpation of the Orbital Lacrymal Glands for Incurable Lacrymation in Cases of Granular Conjunctivitis.—Truc (*Arch. d'ophthal.*, July–August, 1889) draws the following conclusions from his observations: 1. In certain cases incurable lacrymation and granular conjunctivitis are intimately connected together, and can not be cured in any other way than by extirpation of the orbital portion of the lacrymal gland. 2. This operation immediately puts a stop to the epiphora, and causes a rapid amelioration in the granular conjunctivitis. 3. The extirpation of the lacrymal gland is of great value in incurable lacrymation, and is especially indicated in old or chronic granular conjunctivitis with stenosis of the lacrymal passages.

Anomalies of Development of the Eyes in an Epencephalic Monster, accompanied by an Orbito-buccal Hare-lip.—Panas (*Arch. d'ophthal.*, September–October, 1889) gives the following anatomical description of a rare case: 1. The orbito-buccal hare-lip results from the non-union of the embryonic lacrymal fissure. 2. The ascending apophysis of the superior maxilla, which forms such a large part of the excretory lacrymal passages, arises from the external frontal bud or boss, and does not unite with the body of the superior maxilla until much later. Hence this apophysis belongs to the intermaxillary bone and not to the superior maxilla. 3. The presence of two amniotic bands on both corneæ can not be doubted, and it is curious to note the correlation of this fact with the malformation of the two eyeballs and with the presence of a dermoid growth upon the microphthalmic right eye.

A Clinical Study of Some Sympathetic Affections of the Eyes; their Treatment by Massage of the Painful Points.—Chibret (*Arch. d'ophthal.*, September–October, 1889) presents the following conclusions: 1. There are certain sympathetic affections of the eye, especially keratitis and iritis, which have been hitherto unrecognized. 2. These diseases resist all the usual methods of treatment. 3. They may attack either the cornea or the iris. 4. They are always painful, and sometimes excessively so. 5. The essential characteristic of these affections is that the points of emergence of the supra-orbital or external nasal are very painful. 6. Massage of the points of emergence of these nerves always causes a diminution of the pain and an immediate amelioration of the sympathetic affection, no matter how chronic it may be. 7. The laceration or elongation of these nerves would probably bring about an equally good result.

The Connection between Diseases of the Eyes and Diseases of the Nose.—Despagnet (*Rec. d'ophthal.*, September, 1889) considers that many cases of obstinate lacrymation are due to trouble in the nose. In all these cases we meet with a hypertrophy of the inferior turbinated bones which compresses the end of the nasal duct and finally obstructs it altogether. When this condition is relieved the lacrymation disappears. He recommends the galvano-cautery for the treatment of this hypertrophy. Many cases of granular conjunctivitis and keratitis are due entirely to the existence of a catarrhal rhinitis. Secretions from this conjunctivitis and this form of rhinitis have been examined microscopically, and a special microbe has been discovered, which has been cultivated.

Suture of the Cornea in Extraction of Cataract.—Mendoza (*Rec. d'ophthal.*, September, 1889) thus formulates the advantages of this method of operating: 1. It absolutely prevents incarceration and hernia of the iris. 2. It avoids the irritation which is caused by prolonged closure of the lids, and, by permitting free motion to the lids, facilitates the removal of the secretions and thus keeps the eye in a more complete condition of asepsis. 3. It brings about perfect coaptation of the edges of the corneal wound. 4. The latter may thus be kept clean much more readily. 5. When irrigation of the anterior chamber is indicated it is rendered more easy and less dangerous by the possibility of half opening the wound by pulling on the thread of the inferior flap. 6. It admits of the eye being left without occluding bandage immediately after the operation, when inflammation of the lids or of the lacrymal sac necessitates frequent cleansing. 7. The prompt re-establishment of the anterior chamber renders possible the use of atropine soon after the operation without any danger of inducing hernia of the iris. 8. The patient is enabled to be out of bed soon after the operation, or, at the latest, on the next day. 9. There is no danger of re-opening of the corneal wound.

The Number and Caliber of Nerve Fibers in the Oculomotorius in the New-born and Adult Cat.—Schiller (*Rec. d'ophthal.*, October, 1889) concludes from his investigations that the number of the fibers of the oculomotorius of the cat increases but little or none during life. The apparently somewhat increased number of fibers found in the adult cat is probably due to the fact that in the new-born animal some fibers

are overlooked in the counting owing to their extreme tenuity, and that they are confounded with the neuroglia. The caliber of the fibers in the adult animal is from six to eight times greater than in the new-born animal. Forel adds that a continuation of these investigations will probably end in proving that the number of the cellular elements of the cerebro-spinal nervous system does not increase during life. These investigations have also strengthened the belief that there are no anastomoses, either large or small, in the nerve centers, and that each nerve fiber is but the prolongation of one cell, and ends in free arborescent filaments. This would imply a nerve force reacting from one nerve element to another by contiguity or simple proximity, the nerve fiber conducting this influence from its cellule to the point of its terminal ramification, or *vice versa*.

The Treatment of Circumorbital and Ocular Migraine.—Galezowski (*Rec. d'ophthal.*, October, 1889) strongly recommends the use of static electricity in the treatment of migraine. The attack, even at its height, disappears immediately after the application of the current, even when the sitting has lasted only ten minutes. Of course, the neuralgia must be idiopathic if any beneficial result is to be gained from electricity.

The Relative Importance of the Different Forms of Refractive and Muscular Error in the Causation of Headache.—Marlow (*Ophth. Rev.*, December, 1889) draws the following conclusions from a review of his cases: 1. Headaches are frequently the result of errors of refraction and muscular insufficiency. 2. Refractive error or ametropia is a more common factor in the production of headaches than muscular defect. 3. Defective muscular action or insufficiency is more certain to produce headache than ametropia. 4. Astigmatism is the most powerful and common refractive factor in the production of headaches; and, of the different forms of astigmatism, compound hypermetropic astigmatism is the most important in this regard. 5. A combination of insufficiency of the internus or externus with overbalance of the superior rectus is a common variety of muscular defect. 6. Overbalance of the superior rectus is decidedly more certain to produce headache than any other form of muscular defect or of ametropia. 7. A combination of overbalance of the superior rectus with astigmatism is the most powerful cause of ocular headache.

Recovery from Hemianopsia, with Subsequent Necropsy.—Doyne (*Ophth. Rev.*, December, 1889) reports a case of an old man who had a sudden attack of right homonymous hemianopsia. The fields of vision recovered in the course of two weeks, but subsequently a quadrant of the opposite side of each field was lost. Death occurred some weeks later from cerebral apoplexy. At the autopsy, in addition to the extensive extravasations which caused death, there was found asymmetrical softening on both sides of the brain in the cortex of the occipital lobe, one evidently more recent than the other.

Homonymous Hemianopsia; Recovery; Subsequent Death and Necropsy.—Anderson (*Ophth. Rev.*, December, 1889) reports the case of a man, aged forty-one, who complained of failure of vision for six weeks, with severe frontal headache, much failure of memory, and mental depression. He could not see to the right side, and his speech had altered. No loss of gross motor power or of general or special sensation, except as regards vision. The gait and reflexes were normal. The ocular and pupillary movements were normal, and the media and fundus were healthy. Vision and accommodation were normal. The right halves of both visual fields were lost up to, but not including, the line through the fixation point. Anderson concluded that the patient had an intracranial growth, situated in the medulla of the left occipital lobe, and that a hæmorrhage had taken place into the tumor recently. Within two weeks the headache and mental symptoms had much subsided, and there was only very slight contraction of the right halves of the visual fields. Two months subsequently he had a transient attack of left hemiplegia, which soon passed off. Three weeks after the occurrence of the hemiplegia the lower quadrants of the right halves of both visual fields were deficient nearly to the vertical line through the fixation point. Vision was still good, and the fundus was normal. Rapid mental deterioration ensued, and he died, demented, three months later. There was a recent blood-clot in the posterior cornu of the left lateral ventricle, with hæmorrhage and softening of the tissue external to this, involving the whole of the angular gyrus up to its surface. The angular gyrus was replaced by gliomatous tissue.

The Size of the Cornea in Relation to Age, Sex, Refraction, and Primary Glaucoma.—Priestley Smith (*Ophth. Rev.*, December, 1889) gives an account of certain facts obtained by measurement of the cornea in a large number of human eyes. The normal cornea was examined in a thousand eyes, representing all periods of life from five to ninety years. Age, sex, and refraction were noted in every case. It was found that the cornea attained its full diameter very early in life—many years before the rest of the body completed its growth. The development of the cornea is also precocious in relation to that of the eye as a whole. Classification according to sex showed a slight but probably real difference in each life period, the cornea of the male being, on the average, about one tenth of a millimetre the larger. Classification according to refraction showed the unexpected fact that the size of the cornea bears no relation to the refraction, being no smaller in hypermetropia, no larger in myopia, than in emmetropia. This was further proved by comparison of ninety highly hypermetropic with ninety highly myopic eyes. The size of the cornea is determined early in life, and is not affected by the greater or smaller extension of the posterior hemisphere which may occur later. The cornea is full grown at the age of five years or earlier. Sixty-nine persons having primary glaucoma in one or both eyes were examined. The number of glaucomatous eyes was ninety-nine; healthy eyes, thirty-two. Comparing the glaucoma group with the same life periods in the healthy group, the small corneæ formed twenty-six per cent. of the one and four per cent. of the other. Among the one thousand eyes of healthy persons, there was not one cornea so small as ten millimetres, while there were nine such in the much smaller glaucoma group. A definite relation between the small cornea and primary glaucoma was thus proved to exist. The explanation lay in an undue proximity between the lens and the surrounding structures. Further observations show that the smallness of the cornea precedes the glaucoma and is not caused by it.

How far forward is the Fundus Visible with the Ophthalmoscope?—Groenouw (*Arch. für Ophthal.*, xxxv, 3) answers this question as follows: The anterior limit of the fundus visible with the ophthalmoscope lies about 8·5 millimetres behind the margin of the cornea; in myopes somewhat farther; in hypermetropes somewhat less. The possible error scarcely amounts to more than one millimetre in all these three conditions. In aphakia this distance is reduced to 6·5 millimetres.

The Treatment of Symblepharon.—Snellen (*Ophth. Rev.*, December, 1889) describes an operation for the cure of symblepharon which has given very satisfactory results. His plan is to thoroughly free the adherent lid, leaving any conjunctiva present attached to the globe. A thin flap of skin of the required size is then dissected from the cheek, having a narrow pedicle close to the border of the lid near the outer canthus; a button-hole being made beneath this flap from the inner surface of the eyelid, the flap is drawn through and attached to the raw surface of the lid. The operation has proved of value also in enlarging a socket for the reception of an artificial eye.

A New Operation for Ptosis.—Snellen (*Ophth. Rev.*, December, 1889) has recently adopted the following operation for cases of ptosis. A ligature is passed from without inward through the entire thickness of the lid at the upper edge of the tarsus; the lid is then everted and the needle passed outward through all the tissues, except the skin, at a point near the upper limit of the conjunctival sac, and made to perforate the skin near the original puncture. The ends of the ligature are then tied over beads on the surface of the lid. Three such ligatures are employed, disposed rather toward the nasal side, on account of the position of the levator.

The Treatment of Episcleritis.—Snellen (*Ophth. Rev.*, December, 1889) recommends the injection, once or twice a week, of a solution of corrosive sublimate (1 to 5,000) beneath the swollen and thickened conjunctiva and episcleral tissue by means of a Pravaz's syringe, the eye being cocainized.

The Retinal Circulation in Anæmia following Chronic Hæmorrhages and in Chlorosis, and its Dependence upon the Constitution of the Blood.—Raehlmann (*Kl. Mon. f. Aug.*, December, 1889) formulates the following propositions as a result of investigations: 1. In most of the cases which show arterial pulsation the number of corpuscular elements of the blood is, on an average, less than in normal blood; and

that the latter is in many cases markedly diminished, in others slightly, but in all perceptibly. 2. In such cases the individual blood-corpuscles are almost invariably smaller in volume than normal blood-corpuscles. 3. They are generally poorer in hæmoglobin, and consequently specifically lighter, and do not sink as readily in watery solutions as do normal blood-corpuscles, and therefore move more easily and rapidly in such solutions. 4. In many cases of anæmia, which show a typical marked pulsation in the retinal arteries, all three factors exist, viz.: diminution in the number of the corpuscles, loss of hæmoglobin, and diminution in their weight and volume.

Ophthalmoscopic Appearances at the Periphery of the Fundus.—Magnus (*Arch. für Ophthal.*, xxxv, 3) draws the following conclusions from his observations: 1. The ciliary body is partially visible on ophthalmoscopic examination, and appears as a peripheral pigmented band with a radiate or shaggy margin. 2. The region encroaching posteriorly on the margin of the ciliary body is very often of a much brighter color than the rest of the fundus. In this discolored peripheral zone very many fine parallel choroidal vessels are usually visible. 3. At the periphery of the fundus, along the border of the ciliary body, we meet with peculiar pathological foci in an otherwise normal fundus, both in young and old persons. 4. These foci appear either as small oval or circular white spots, or as a network of fine white lines, or they blend into a broad belt surrounding the entire periphery of the fundus. 5. In the region of these foci pigment is usually present, arranged with a certain regularity around the peripheral border of the diseased focus. 6. In the eyes of young persons the cause of these pathological appearances is usually found to be a high degree of myopia. 7. In a highly myopic eye the peripherical atrophic belt is a characteristic appearance. 8. Posterior staphyloma and changes at the periphery of the fundus usually appear together in most of the cases. 9. In the eyes of old people, if they are not highly myopic, these peripherical foci are senile changes.

The Ætiology of Neuroparalytic Keratitis.—Von Hippel (*Arch. für Ophthal.*, xxxv, 3) draws the following conclusions from his investigations: 1. The theory of the existence of trophic fibers running in the center of the trigeminus can not be harmonized with the results of many autopsies. 2. The purely traumatic theory of causation is untenable. 3. The theory of evaporation is capable of explaining the appearance of the inflammation in every case. 4. A diminished power of resistance to injuries does not exist. A non-sensitive eye is more exposed to desiccation from evaporation than a normal eye. 5. A wire network has the power of directly hindering the evaporation. 6. A wire guard can not, however, prevent the occurrence of inflammation. 7. A moist atmosphere hinders the appearance of neuroparalytic keratitis. 8. Micro-organisms are not always found, and can not therefore be regarded as an ætiological factor.

Miscellany.

Sound Advice for the Profession.—The following lay sermon to the profession is to be found in the preface of a curious old medical work entitled *Vade Mecam or a Companion for a Chirurgion fitted for times of peace and war, by Thomas Brugis, Doctor in Physick. London. Printed by T. H. for Thomas Williams, at the sign of the Bible in Little Britain, 1652.*

"Presume not too much on thy own wisdome and vertue, lest thou beest lifted up with a vain confidence, and puffed up with pride, for when men are carried with an inordinate and blind love of themselves, they are soon persuaded that there is nothing in them worthy to be dispised, yea, they think that their ignorance is wisdom, insomuch that knowing nothing, they suppose they know all things, and having no dexterity to performe any one commendable work, they presume very inconsiderately to set their hand to every great matter; but the more care and diligence they bestow, being let with a desire to shew great skill, and thinking to win honour and renown, so much the more they discover their ignorance and blockishnesse, purchasing to themselves shame and infamy: For a man to know himself to be ignorant, is the best science and necessary for men, that without it they cannot be truly skillfull; for as I said before, the ignorant person that knoweth not himselfe to be such an one, but supposeth he knoweth that which he doth not, indeed is as unteachable as a beast can be" . . .

"Socrates, who by the oracle was declared to be the wisest man then living, was greatly commended by the ancients, because he said he knew but onely one thing: viz., That he was ignorant and knew nothing.

"Now a word or two to the patient: Thou seest in every village a sort of Mountebanks, Empericks, Quacksalvers, Paracelsians (as they call themselves), Wizards. Alcumists, Poor vicars, east apothecaries, and physitians men. Barbers and Good wives that professe great skill go with the name of Doctor, which title perhaps they bought at some beyond sea University, where they bestow this degree upon such people for their money; the phrase they use is 'Accipiamus pecuniam, demittamus asinum,' and so with title of Doctor Asse; away he flies into all countries possessing the people with stories and false tales, and leads them to the destruction of their bodies, if not of souls too, that an able Physitian or Chyrurgion, who hath undergone a great deal of hardship to benefit himself in his art can scarcely maintain himself, or know who shall be his patients."

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

HYPERTROPHY OF THE PROSTATE GLAND.

AN ADDITION TO McGUIRE'S OPERATION.*

BY ROBERT T. MORRIS, M.D.

GENTLEMEN: This patient, who is about sixty years of age, is suffering from an obstruction at the neck of the bladder. For more than a year he has been obliged to draw his urine with a catheter, and lately it has become a difficult matter for him to pass the instrument into the bladder. The patient has been under the care of a well-known general practitioner, who has exhausted the ordinary resources for relief in such cases, and now that the patient is suffering from an aggravated chronic cystitis, with frequently recurring septic symptoms, he asks for the adoption of radical measures for relief.

For the past two days the patient has been under preparatory treatment. His bowels have been opened freely in order to facilitate the elimination of septic products through the emunctories. Hot tobacco fomentations have been applied over the hypogastric region for the purpose of quieting the inflamed and irritable bladder, and I know of nothing else so effective. A leaf of tobacco is moistened in hot water and placed over the hypogastric region. A towel wrung out in hot water is placed over the tobacco, and over all we need some material like oiled silk or dry brown wrapping-paper, to prevent evaporation.

In order to limit fermentation of the urine, the patient has been given ten grains each of boric and benzoic acids internally three times a day, and his muddy urine has cleared up very nicely under this practical internal antiseptic treatment. In addition to the steps which have been employed in this case, it is usually a good plan to have the patient draw his urine at least once daily while he is in the knee-elbow position, for by this procedure he can remove residual urine that could not otherwise be obtained.

I will not stop to explain the differential diagnosis between tumors of the bladder and prostatic hypertrophy, but will state that in this case the lateral lobes are markedly but evenly enlarged. It is not the size of the gland that causes disturbance, but the character of the enlargement. A few men possess a series of prostatic tubules dorsad of the urethra, which form the so-called third lobe, and when we have median centric hypertrophy, a small third lobe may act as a ball valve in shutting off the entrance to the urethra. Then, again, when one of the lateral lobes is much larger than its fellow, a tortuous urethral canal must be the result, and it frequently requires much skill to pass an instrument into the bladder. In addition to the obstacles enumerated, we often find the mouths of the prostatic ducts so much enlarged that they will admit the tip of a catheter, and no one but the specialist knows what dangers await the patient if he is to have numerous examiners.

* Abstract of a lecture delivered at the Post-graduate Medical School, May, 1890.

The prostate gland in various animals develops and degenerates coincidently with the testicles, and it is at about the time when the testicles normally atrophy in man that prostatic hypertrophy occurs. This condition is found in a relatively small number of men, however, and is really a degenerative process, consisting in elongation of the prostatic tubules and increase in the unstriped muscular fibers, the prostatic secretion at the same time becoming thin and watery. As degeneration continues, the tubules and muscular fibers are replaced by connective tissue, and when this process occurs in limited areas we have the so-called fibrous tumors of the prostate which are sometimes supposed to be homologous to fibroid tumors of the sister organ.

The patient now being fully under the influence of ether, I pass a double-current catheter into the bladder and wash it clean with a copious stream of Thiersch's solution (salicylic acid, gr. j; boric acid, gr. v; water, f ℥ j).

The stop-cock on the discharge pipe of the catheter is then closed and the bladder fills with about twelve ounces of the solution, which is allowed to remain.

A rubber bag which will hold twelve ounces of water is oiled, slipped into the lower rectum, and then distended with air, so that on percussing the abdomen I find that the fundus of the distended bladder has been carried well above the pubes by the lifting bag in the rectum. The skin about the pubic region has been previously shaved and scrubbed with bichloride-of-mercury solution, and inserting the knife through this clean skin just over the symphysis pubis, I make a cephalad incision four inches in length. The next cut severs the tissues of the linea alba and the transversalis fascia and exposes loose fat which lies upon the bladder. This is picked up and snipped away with scissors in such a careful way that the surrounding areolar tissues are not disturbed, for we must remember that urine would enter a little rent and infiltration might lead to failure of the operation. The danger of opening the peritonæum is spoken of only by authors who have not had an opportunity to look at the peritonæum in this region. The next step in the operation consists in passing a couple of temporary sutures through the muscular wall of the bladder and fastening them to the skin in order to prevent the bladder from dropping back out of sight when the fluid which distends it runs out. The scalpel is now passed through the bladder wall at a low median ventrad point, and my finger instantly inserted into the opening prevents the escape of fluid until I can explore the interior of the distended bladder. There is no calculus to be found. Phosphatic calculi are very much commoner in these cases of enlarged prostate than is generally supposed, because various salts are precipitated when the residual urine ferments and becomes strongly alkaline. Many a practitioner is to-day baffled by a case of catarrhal cystitis in conjunction with an hypertrophied prostate, because he does not suspect that calculi have formed in the patient's bladder.

This patient has an unusually hypertrophied third lobe to his prostate, and there is no well-defined pedicle. Otherwise I should enucleate the third lobe, leave the abdominal fistula open temporarily, and expect that the patient would.

pass his urine by the normal route a few weeks later. It will be safer here to make a permanent suprapubic urethra. Hunter McGuire opens the bladder at the lowest available median ventrad point, and leaves open the cephalad extremity of the abdominal incision. The abdominal wound then being sutured elsewhere, we have left a fistula two or three inches in length, the walls of which are kept in apposition by the abdominal wall caudad to the external opening of the fistula, so that the patient can retain his urine or pass it at will. The suprapubic urethra in McGuire's operation is composed of cicatricial tissues, and it is difficult to tell just how far contraction will proceed, and I suppose that the region of the tract is apt to remain in a sensitive condition. In order to overcome these objections, I shall now resort to a plan which has not been tried before, so far as I know, and which may never be tried again. My original abdominal incision through the skin is lengthened two inches. A ribbon of skin and subcutaneous fat about three inches long and one third of an inch broad is dissected away from either side of the abdominal incision, leaving the caudad extremities of the ribbons attached. The free ends of the ribbons are now sutured with fine catgut to the mucous membrane of the bladder wound, each on its respective side. The temporary sutures which held the bladder up are now cut, and as the bladder drops down, it takes with it the two ribbons of skin, which lie prettily face to face, and which are to form a soft urethra of skin. Iodoform is now rubbed gently into the deep portions of the wound, because it will make a thin, firm protective coagulum with lymph, and turn aside urine that might otherwise infiltrate the tissues. The wounds of the abdominal wall are now closed with catgut, leaving room for drainage about the fistula. A short rubber drainage-tube is introduced into the bladder, and this will be left in place for forty-eight hours, the patient lying upon his side or abdomen during this time, or until plastic lymph has sealed the wound securely against infiltration of urine.

The patient will be given ten grains each of boric and benzoic acids internally for several days, and the urine will by this means be converted into a "healing" fluid.

Note.—Four weeks after the operation the patient had made an uneventful recovery, and all of the sutured abdominal wounds healed by primary union. The ribbons of skin now form a soft, round urethra. The patient can retain his urine or pass it at will, and he substitutes a glass drainage-tube for the penis, pressing one end of the tube against the suprapubic meatus and passing urine through it. In order to do this, he makes an ordinary expulsive effort, and no urine passes by way of the penis.

Bismuth Salts and the Odor of Garlic.—"The cause of the odor of garlic occasionally communicated to the breath of patients who are taking preparations of bismuth is said to be the presence of the metal tellurium as an impurity. The fact that tellurium gives this odor to the breath was first noticed by Sir James Simpson, who, when making trials of the salts of cerium, also experimented upon tellurium. He reports a case of a divinity student who inadvertently got a dose of tellurium which was followed by the evolution of such a persistent odor of garlic that for the remainder of the session the patient had to sit apart from his fellows. That specimens of bismuth preparations, which caused this peculiar odor of breath, contained tellurium was established in 1875. The British Pharmacopœia guards against this impurity by giving a special test for its detection in bismuthum purificatum."—*British Medical Journal.*

Original Communications.

THE GROSS ANATOMY OF CHRONIC PULMONARY CONSUMPTION

IN RELATION TO DIAGNOSIS AND PROGNOSIS.*

By J. WEST ROOSEVELT, M. D.,

VISITING PHYSICIAN TO BELLEVUE AND THE ROOSEVELT HOSPITALS, NEW YORK.

The great importance of making an early diagnosis and correct prognosis in consumption will, I hope, excuse me or adding to an already voluminous literature.

During this century two great observers have done humanity incalculable good; the one, Laennec, by enlarging greatly the possibility of diagnosis, the other, Koch, by demonstrating the essential causal factor of consumption—the bacillus. The evidence of the existence of consumption afforded by the discovery of this bacillus in the sputa is naturally absolutely unassailable. The absence of the bacteria, however, even when the examinations are made by an expert, must always leave a doubt in the mind as to whether tubercular disease may be excluded or not. There are so many important precautions to be observed before the absence of bacilli can fairly be held to exclude consumption that one must be very careful in estimating the value of negative observations; moreover, one must not waste too much valuable time in examining sputa, for it must always be remembered that not the bacilli in the sputa are to be feared, but those remaining in the lungs. Therefore, one should not give the latter a good chance to increase while looking for the former.

To exclude consumption by negative results obtained in searching for bacilli, it is necessary, first, that the examination be made by an expert with a good microscope and good dyes; second, that a sufficient quantity of sputum be obtained; third, that a very large number of observations extending over a considerable time be made. Some patients do not expectorate, and in these no examination is possible. In some the sputa are very scanty. In all, time is very valuable. Frequently it happens that no expert is at hand. By "expert" I mean a person trained by long practice to make the observations. If any one of the conditions enumerated be unfulfilled, the result is of no practical value. One must be able to rely upon the observer's skill. Any one not *frequently* making examinations of sputa is not fit to make any. The aniline dyes used must be known to be capable of staining. The lens employed must be sufficiently powerful and must be optically very perfect. The sputum must be that *coughed up*, not merely, as often happens, saliva and mucus from the naso-pharynx and mouth. It must also be as fresh as possible. Cover glasses must be thinly and evenly spread, the number examined must be very great, and each must be systematically examined so that every part is seen.

The importance of thoroughly appreciating these points is my excuse for dwelling upon them. That they are not

---

* Read before the Section in Practice of the New York Academy of Medicine, May 20, 1890.

always known to medical men almost any one who has had much experience will admit, since he probably has, at different times, received saliva, vomit, and miscellaneous dirt (such as orange-pits and many other things), all of which are called "sputa," and has been asked to pass judgment upon them. If he objects, quite often both he and pathologists in general are severely censured as useless dreamers by "the busy practitioner" who has perpetrated the outrage. It rarely occurs to the said practitioner that he may himself be at fault. It is much the same with the practical man, physician or surgeon, when he sends small fragments of something in various peculiar fluids—often most ingeniously devised, if the absolute destruction of all recognizable histological elements is desired—without any history, or with a most imperfect one, to a pathologist with a request for a diagnosis at once. He is personally aggrieved if the pathologist demurs, and he feels that pathology is not worth much after all! It would be well if the information was more widely spread that, in general, alcohol is the best preservative for tumors, etc., and that a history must accompany the specimen, and that, for sputum, clean bottles are advisable. Then physicians would not (as has occurred in the author's experience) send tumors in blood, brine, glycerin, or carbolic acid, or send sputum in a dirty piece of toilet paper, twisted up at the ends, or an old pill box!

It was natural that the results of the labors both of Koch and Laennec should have been misjudged, especially in respect to their value as negative evidence. In each case their value as positive evidence was enormous, the bacillus indeed affording, so far as we know, absolute proof. Positive evidence is that naturally first sought. The history of most important additions to scientific knowledge is much the same. First the facts are made public by the discoverer. Next the truth of his statements is denied by many. Then, after a longer or shorter time, scientific public opinion admits the facts, and usually tries to fit them to all sorts of preposterous theoretical notions. Almost always the first general idea after accepting the facts is to see what they positively prove to exist. Long after this comes the question of what they do *not* demonstrate.

In medicine, where so much is vague, resting upon personal observation, the absence of anything which is positive evidence is peculiarly apt to be regarded as far too valuable negative evidence. The question, for example, presented in most cases is, "*Has* this person consumption?" not "Can you say that this person *has not* consumption?" Too often the absence of facts enabling us to answer "Yes" to the first question is regarded as justifying us in replying to the second, "He has not!" Nothing can be more irrational than such reasoning, yet it is not uncommon.

Of both Laennec's and Koch's discoveries it may be said that their value as positive evidence is so great that their importance in excluding disease has been overestimated. The work of both has also another point of resemblance since each, in his sphere, seems to have presented it completed to the world. No important fact has yet been added to the observations of either, although the theoretical explanation of these observations may be disputed. It may be added that the practical value of the work of both is not even yet widely understood. I desire to present certain anatomical facts bearing upon it.

Clinical Classification of Cases based upon the Gross Anatomy of the Lesions.

In this paper we have nothing to do with the finer details of pathological anatomy. The reader is perfectly free to regard the tubercle bacillus as the cause of the disease, or the result, if he prefer. He may, if he wishes, think that the "cussedness" of the disorder is such that it would be just like it to create a new organism to deceive men. He may speak of "catarrhal" or "pneumonic" or any other sort of phthisis; and, if he so wills, may think that the "catarrh" or "pneumonia," or what not, is sufficiently peculiar to make (in a sort of wanton pathological playfulness) things looking and acting like tubercles, and then add tubercle bacilli to these, for the further mystification of scientists. He is at liberty to believe all these or to adopt almost any other theory; but he must admit certain things if he wishes to understand the point of view of the writer. These are—

1. The discovery of tubercle bacilli in sputum furnishes positive evidence of consumption or of tuberculosis somewhere in the air passages or mouth.

2. Chronic consumption of the lungs occurs sometimes in a form in which the lesions consist of more or less distantly separated small nodules, and sometimes in a form in which there is a more or less widespread diffuse solidification of the lung. In either of these forms cavities may be found. In both, the lesion first invades, in a large majority of cases, the apices of the lungs.

The anatomical classification is adopted for diagnostic and prognostic purposes. It does not pretend to be of value to the pathologist, nor does it in the least regard the question of how the lesions are produced. It looks only at physical conditions, and the relation of these to examination by physical means. The class characterized by the formation of nodules I shall call "the discrete form." The class in which solidification of considerable portions of the lungs occurs will be called "the diffuse form." The first embraces those cases which Professor Delafield puts in the first division of the class which he calls chronic miliary tuberculosis* in his admirable study of the anatomy of consumption. It also embraces certain cases which are contained in Delafield's second subdivision of chronic miliary tuberculosis, in which, besides tubercles, there is new fibrous tissue. It is intended to mean any form of consumption in which the lesion produces but little solidification of the parts invaded. The "diffuse form," for the purposes of this paper, includes all cases in which the lesion is such as to solidify considerable portions of the lung in mass. Certain cases of Delafield's second division of chronic miliary tuberculosis are included for convenience in it just as certain lesions much more complex than miliary tubercular inflammation are included in the "discrete form." I repeat that my classification does not pretend to histologi-

* Delafield, *Studies in Path. Anat.*, p. 87. William Wood & Co., New York.

cal accuracy; it is convenient, I think, for diagnostic purposes.

The Discrete Form presents itself, in New York at least, very often to the observer. In it we find scattered nodules varying in size from that of the conventional millet-seed to that of a pea. These nodules are separated by lung tissue, which is physically normal or emphysematous—*i. e.*, capable of expansion and contraction and of causing air-currents in the same way and under the same physical circumstances as healthy or as emphysematous lung. In advanced cases the nodules may break down and form cavities, usually of small size. When the nodules become sufficiently numerous the lung is practically solidified; but this occurs only late in the course of the disease.

With the formation of discrete nodules there is usually more or less bronchitis and pleurisy. There is also commonly some emphysema, generally of the kind called "compensatory." This emphysema is, it seems to the writer, an example of what he believes to be rare in most other conditions—dilatation of the air-vesicles and passages caused by mechanical over-distension. It seems very probable that as the elasticity of a larger or smaller part of the pulmonary parenchyma is destroyed by the growth of new tissue, the thoracic expansion causes a negative pressure in the parts not affected, which is much greater than normal. Let us suppose that one third of the parenchyma of a lung is, by reason of this solidification in discrete nodules, rendered non-elastic and impermeable to air. Let us disregard the other lung or suppose that one third of it is similarly affected. If the expansion of the chest is the same as in health, then the permeable vesicles must during inspiration dilate one third more than in health. The fact that emphysema is frequently limited to those portions of the lung near the nodules is explained by the pleural adhesions, which cause that part to follow closely the movement of the nearest ribs. If there were no such adhesions the emphysema would be more evenly distributed throughout the whole lung. The chest movement is actually, of course, more or less restricted in these cases. The assumption that it is normal is only made for the sake of simplicity.

Besides this mechanical cause of the emphysema, it is possible that some obstruction to the circulation is produced by the nodules and that atrophy from lack of nutrition results. In certain cases, of course, the tubercular process takes place in lungs already emphysematous, for emphysema does not protect from consumption.

The Diffuse Form.—In this class the important clinical fact is that consolidation of the lung tissue occurs and produces, at a much earlier stage than in the discrete form, recognizable physical signs. It has another important clinical distinction in a large number of cases; the physical signs correspond pretty closely to the patient's actual condition and give a much more accurate idea of the severity and progress of the disease.

The consolidated tissue consists sometimes entirely of dense connective tissue. Sometimes patches of coagulation necrosis, diffuse tubercle, interstitial pneumonia, bronchopneumonia, and peribronchitis are mixed in varying proportions in it. In advanced cases cavities form. With this, as with the "discrete form," there is usually bronchitis and pleurisy, the latter causing adhesions between the pleural surfaces.

The Discrete and Diffuse Forms contrasted.—The clinical value of the classification, temporarily adopted, is that it recognizes the existence of cases in which the physical signs bear no relation to the extent of the lesion—cases, moreover, in which the bacillus is very likely not to be found, at an early period, in the sputa.

In some of these there is at first no expectoration, and therefore the bacillus is not to be discovered. In some the expectoration is scanty. As the nodules in which the bacilli grow are scattered (and frequently not in direct communication with the air passages), it may easily happen that for a long time no bacilli are expectorated. The discrete form furnishes cases fondly believed by many laryngologists to be examples of primary tubercular disease of the larynx. It has also furnished to the writer some cases which he thought to be broncho-pneumonia, and some which he supposed were substantive emphysema. It has also caused much doubt in regard to diagnosis, both in its earlier and later stages. At the present time the bacillus (unfortunately often too late) may give evidence unimpeachable of the disease. So far as the writer has observed, bacilli are found sooner or later in every case properly examined.

The "diffuse form" not only is apt to give fairly marked physical signs at an early date, but also (as the consolidation is accompanied by considerable liquid exudation, which soon enters the bronchi) at an earlier date are the bacilli apt to appear in the sputa. They are also apt to be more abundant from the first.

To illustrate, let us suppose that there is in the right upper lobe a lesion of the "discrete form." The lesion we will say consists of nodules scattered throughout the upper third of the lobe, each nodule not more than an eighth of an inch in diameter, and the average distance between them about half an inch. Let us also say that the nodules are closer together at the extreme apex and more widely separated lower down, and that there is enough pleurisy to have caused adhesion of the pleural surfaces at the extreme apex. Let us suppose that there is as yet little softening of the nodules and but slight bronchitis, though there is some emphysema between the nodules.

The anatomical form of this lesion is such that the only physical signs in very many instances would be very slight dullness, with some prolongation of the expiration, and usually some exaggeration of the intensity of both respiratory murmur and voice, or perhaps diminished percussion resonance or slightly tympanitic resonance. The pleural adhesions might or might not give audible evidence of their existence. If they did, when one thinks of the numerous cases of non-phthisical people who are found, post mortem, to have such adhesions, this evidence becomes of little value.

As there is normally over the right apex of many people slight relative dullness, and all the other peculiarities noted, it is very hard positively to estimate the value of any of them.

The bacillus may help us in such a case, *if found;* but it is precisely in such a case that it is most difficult to find. The sputum is scanty or absent. The bacillus is discharged in small numbers, if at all.

These cases are not rare, and the recognition of this serves to emphasize what is probably the most important fact in connection with early diagnosis—namely, that physical examination and negative microscopical examination are to be regarded only after careful study of the clinical history. Percussion and auscultation and the microscopic examination may reveal nothing, yet commencing consumption may be safely assumed to exist from the evidence of the patient's history and general appearance. Much that was written by Walshe so many years ago in regard to early diagnosis is as true to-day as ever, in spite of the great advances of the last few years.*

I have said that the disease "may be safely assumed to exist." This sentence hardly expresses my meaning, though it does state the exact facts. My meaning is that cases occur not infrequently in which tubercle bacilli can not be discovered, and in which physical examination of the chest gives none or very vague abnormal signs; yet *it is the duty of a physician to make a diagnosis of consumption*, and to take proper measures for treatment, no matter at what cost. The chances of consumption being the trouble are so strong that the physician should risk his own reputation, and perhaps cause much inconvenience and pecuniary loss to the patient. Just as it is the duty of a physician to conceal his fears, possibly at the risk of his reputation, in many cases where symptoms are present which may indicate disease (as in glycosuria in pregnancy, for example), but where the chances are very great that these symptoms are merely transitory and unimportant, so is it his duty, when the chances are very great that serious disease exists, to state the facts plainly and truthfully, and, in the case of consumption, even to alarm a patient needlessly, rather than to let him die (equally needlessly) while waiting for positive evidence.

The Discrete Form in Relation to Physical Signs.—In its earliest stages the changes produced by this form are such as to cause but little variation from the normal physical condition of the lungs. The nodules are not large enough, nor are they near enough together, to produce a change in the percussion note sufficiently marked to be recognized. Sometimes they cause slight dullness. Often their presence is indicated only by a note which is more tympanitic than pulmonary in quality, but not always, as far as the writer can judge, higher pitched. This note resembles closely the sound produced by percussion over the patient's trachea. The tympanitic quality of tone heard in some cases over a consolidated and compressed lung is, in the writer's experience, the same as the tracheal note. It is fair to assume that in many instances this type of note is really produced in the trachea, and that the physical changes in the lung are such as either directly to transmit the force of the blow struck to the trachea, or perhaps the scattered nodules, with the altered lung elasticity and altered air capacity together, form a body which resounds in unison with the air in the trachea and large bronchi without modifying very much the note of the latter.

Whatever be the explanation of the phenomena, we find in the early stages of this form of the disease sometimes one sometimes another of the following percussion signs: Dullness, normal or exaggerated pulmonary resonance, or vesiculo-tympanitic or tympanitic resonance, or the cracked-pot sound. The pitch over the affected area may, when the resonance is pulmonary in quality, be higher or lower or the same as that over the corresponding part of the unaffected lung. Later in the disease the increasing number of nodules usually gives rise to dullness more or less marked.

Both vocal resonance and fremitus bear little relation to the percussion note, or indeed to each other. The voice is a poor help in diagnosis in such cases, and should be received only as evidence which gives some weight to other signs.

The respiration is, when bronchitis or pleurisy are very slight or absent, quite often normal. Probably prolongation of the expiratory sound with slight rise in pitch is the earliest recognizable sign. Sometimes there is simply an exaggeration of both inspiratory and expiratory sounds. Sometimes both are feeble and sometimes both are normal. With sufficiently closely grouped nodules the breathing is apt to become somewhat bronchial in quality, and, when the nodules are numerous enough practically to solidify a considerable part of a lobe, the type is often purely bronchial. In certain cases the breathing is cavernous or amphoric, and yet no cavities exist. The latter, when present, may, of course, give bronchial, cavernous, or amphoric breathing.

The presence of pleural adhesions sometimes gives rise to special signs and sometimes does not. In certain cases it seems quite possible that such adhesions cause the so-called "cog-wheel" or "wavy" respiration. In others they may produce—they certainly are coexistent with—fine dry or moist râles. Sometimes, also, they seem to produce "friction," or "stretching," or "tearing" sounds. So often in early cases are the adhesions near the summit of the lung (where relatively little gliding motion of the pleura takes place) that it is easy to understand how frequently their existence is not possible to demonstrate during life.

To the writer the absence of signs due to pleural adhesions, especially near the apices, is perfectly comprehensible. Not so clear, in spite of the positive statements of many observers, are the reasons why many signs, supposed to be produced by these adhesions, should really be caused by them. Why the type of subcrepitant râle, for example, which sounds like the bursting of fine bubbles, should ever be produced by the stretching of tissue, moist or dry, which not only contains no air but is not in contact with any, is not easy to explain. True, there is no positive evidence that the bubbling sound is really produced in the substance of the adhesions. It may be, as some think, in the neighboring lung; but this also is not positively demonstrated. The sound of this type of subcrepitant râle is fairly closely imitated if one listens to the noise caused by rubbing together two pieces of glass moistened with saliva containing air-

* See Walshe, *Diseases of the Lungs*, 4th edition, 1871, p. 475 *et seq.*

bubbles. If the bubbles be carefully excluded there is no râle heard. It has not been demonstrated, as far as I know, that any bubbling sound is actually produced by stretching any elastic substance, whether dry or soaked in fluid, while this substance is placed under conditions which absolutely prevent the aspiration into its tissue of bubbles of air or other gases. There is room for much study upon this subject. It sounds at first plausible that an increase of serum in the pleural adhesions will produce this sound. Yet, we hardly know that it ever does. Neither can we say positively that it does not.

The mechanical results of pleural adhesions, so far as the lung and chest movements are concerned, are, first, that the gliding of the pleural surfaces is more or less restricted over a larger or smaller area; second, that this restriction probably modifies somewhat the direction of expansion of the entire lung as well as those parts of it near the adhesions; third, that in some cases the new tissue forming the adhesions by its contraction tends more or less to deform the chest and restrict its motion, and also to deform the lung.

In spite of very widely distributed and firm adhesions, however, it is possible for the lung seemingly to do its work as well as usual, and no symptoms whatever indicate firm, even complete, union between the pleural surfaces. Complete obliteration of the pleural or of the pericardial cavities is perfectly compatible with apparently undisturbed function of lung or heart. It seems as though the mechanical advantage of these lubricated surfaces, permitting freer movement of the contained organs, is sufficiently great to cause them to remain in the evolution of the race, but not great enough to make them necessary to each individual. In the wonderfully balanced collection of what are, after all, but makeshifts called the human body, the heart or lung crippled by adhesions, is still often able to work well enough to keep the rest of the organs going.

If, in addition to the nodules, there is enough bronchitis, signs of this alone may be found. Signs of bronchitis, with or without emphysema, upon one side of the chest are valuable evidence of consumption. Bronchitis upon one side probably never occurs unless there be some local cause. Especially suspicious are such signs in a young adult who gives a history of cough lasting for some time, with other rational symptoms of consumption.

When the nodules become sufficiently numerous to crowd one another pretty closely, the lung is practically solidified, and the signs become those of solidification. In such instances, however, the disease is far advanced.

It is evident that in this form the physical signs bear but little relation to the extent of the lesion. The diagnosis in early cases must be made without too much regard for the signs. Of the prognosis the same is true. The bacillus also is frequently hard to find. In the patient's general condition and history we have the indications upon which both diagnosis and prognosis must rest.

The Diffuse Form and its Physical Signs.—In this form the solidification of considerable parts of the lung makes the recognition of the disorder in very many cases quite easy. The signs of consolidation become marked quite early. These are well known, and it is not worth while to repeat them in detail. The consolidation gives signs which fairly indicate the progress of the lesion. The bacillus is generally easy to find in the expectoration.

Summary and Conclusions.—1. For clinical purposes we may describe a discrete and a diffuse form of consumption.

2. The discrete form is not at first easy to recognize, since abnormal signs often are absent and the bacillus absent or hard to find. The physical signs in this form are not to be regarded as of value in prognosis, while in the diffuse form they are fairly trustworthy.

3. The diagnosis of commencing consumption must be made from the patient's history, quite as much as from physical examination of the chest or sputa. If we wait too long in order to become certain in diagnosis, we also quite often permit our patient to become certain to die. It is better far to run the risk of making an incorrect diagnosis by concluding that the disease exists when it does not than to run the risk of jeopardizing, or possibly needlessly sacrificing, a life for fear of a diagnostic error.

SUPPURATION OF THE ANTRUM OF HIGHMORE.*

By MOREAU R. BROWN, M. D.,
PROFESSOR OF LARYNGOLOGY AND RHINOLOGY AT THE CHICAGO POLYCLINIC.

Although a complete description of the maxillary antrum was given by Nathaniel Highmore as early as 1601, it was not until two centuries had elapsed that the diseases occurring within the cavity began to attract the attention of surgical writers.

In 1846 there appeared in the published report of the clinical lectures in surgery, delivered at St. George's Hospital by Sir Benjamin Brodie, the first clear and detailed description of diseases of the antrum of which we can find authentic record. In this report the description of "inflammation dependent on local causes, inflammation independent of local causes, collection of transparent fluid in the antrum, polypi of the antrum, and malignant tumors of the antrum," is given in a manner which shows familiarity with the diseases based upon personal experience.

The situation of the antrum of Highmore or the maxillary antrum is found to vary even on different sides of the same face. In general terms, its floor is said to extend above the alveolar process from the second bicuspid tooth backward. Projecting into it are several conical processes corresponding to the first and second molar teeth, and in some cases it is perforated by the roots of these teeth. The antrum is occasionally subdivided by incomplete bony lamellæ, and it is lined with mucous membrane continued from that of the nasal cavities. Its bony walls are thin, particularly the orbital plate, the nasal wall, and the facial wall, above and between the first and second molars and immediately above the canine fossæ. Located in the upper and anterior part of the middle meatus of the nose, and con-

* Read before the Illinois State Medical Association, May 9, 1890.

cealed from view by the middle turbinated body, is the hiatus semilunaris which communicates with the frontal cells and the ostium maxillare.

The term suppuration or empyema of the antrum is used to designate a condition characterized by the formation of pus on the surface of the mucous membrane lining the maxillary sinus. The pathological changes which take place in the mucous membrane of this cavity during the continuance of the morbid process do not differ from those which occur in similar membranes under like conditions.

Causes.—The proportion of cases from dental complications to those from other sources is as yet an undetermined question. A large percentage of those which fall under the observation of the dentist owe their origin to diseases of the dental arch, whereas these disturbances play a more secondary part in the cases which are met with by the rhinologist. Bosworth contends, and with apparent cause, that hypertrophy of the middle turbinated body and other obstructions to the ostium maxillare will interfere with the outflow of the secretion, the accumulation of which, in a closed cavity, results in a purulent discharge. Among other causes are tumors within the antrum, blows upon the cheek, injury to the teeth, and division of the infra-orbital nerve. Observation on the subject has led me to ascribe to the disturbance to health which we call "taking cold" a more prominent position in the list of causes than is generally allowed to it.

A tabulated statement shows that out of twenty-one antra which were involved, nine were considered to have been of this origin. These cases were under observation from their commencement until relieved by treatment. A majority of the patients had been under my professional care prior to the antral disorder, and hence I am able to state positively that there was no evidence of a former suppuration. There was one point, however, which may be worth mentioning as possibly having exerted some influence over the production of the inflammation—namely, the prevalence of the epidemic of *la grippe*. In two of the cases suppuration followed directly upon an attack of this disease.

The lining membrane of the antrum participates in the inflammatory process resulting from catching cold in a similar manner to that of the Eustachian tube. After the cold has passed, the inflammation and suppuration, should it have reached that stage of purulency, may disappear, and the membrane return to its former condition, minus a certain amount of its normal ability to withstand such disturbances. Repeated attacks of this nature soon lead to the chronic form of the disorder.

Symptoms.—Should the inflammation be acute, there will be pain and tenderness with a sense of weight and fullness over the antrum and with pressure up against the eye, hyperæmia of the ocular conjunctiva, and sensitiveness of the teeth, especially noticed on masticating. The pain is increased by stooping over, and is worse in the morning.

If the inflammation owes its origin to dental complications, the symptoms indicative of these disorders are added to the above; or if it be the nasal mucous membrane that is affected, those of the coryza are also present. Should the natural outlet of the sinus become closed, as it frequently does from swelling of its lining membrane, the pain increases and the face is more tender.

The formation of pus, which is announced by a chill, causes distension of the walls, which may produce disturbance of vision by pressing on the orbital plate, and a tumor-like projection forms over the thinnest walls. Unless surgically relieved, spontaneous evacuation takes place. If the natural opening of the antrum into the nose remains free, the pus finds a ready outlet through this channel, and the irritation caused thereby to the delicate mucous membrane may produce an obstinate turgescence of the turbinated bodies and occlusion of the nasal passage. The purulent discharge will either gradually diminish and finally, in the course of a few days, cease altogether, as is witnessed sometimes in coryza, or it may continue in diminished quantity, and all symptoms of a painful nature disappear. The latter is more apt to occur in cases from dental complications. The discharge now takes place into the nose at intervals during the day, particularly shortly after arising from bed in the morning, or on stooping over; also when lying down if the position of the head be changed, as on turning from the affected to the sound side. In this (now chronic) form of the disease, although turgescence of the turbinated bodies seldom occurs from the irritation produced by the pus, yet it has been observed to exist in a very persistent form. And that hypertrophy may thus be brought on, or an existing hypertrophy aggravated, I can bear personal witness to. I therefore believe that the hypertrophy of the middle turbinated body, and possibly the polypoid growths so often seen in connection with chronic empyema, are rather a result than a cause.

When the dental arch has been the cause of the purulency, the pus is of a very offensive odor, the opposite of what prevailed in several of the acute cases reported in my table from catching cold. Extension of the disease into the neighboring cavities, and even death, has been noted among the rarer events.

Diagnosis.—In acute suppuration we are so aided in the diagnosis by the history of the case that, with ordinary care, the disorder can readily be recognized. In chronic empyema a discharge which is influenced by position is observed by the patient to come from the nose. By carefully inspecting the nasal cavity we shall often find pus; it may be but a thin film on the anterior and inferior part of the middle turbinated body, or between it and the outer and inner wall. When wiped away, fresh pus can occasionally be made to appear by changing the position of the head or pressing upon the thin walls of the antrum.

Voltolini's method, as described and brought to greater perfection by Heryng, is of undoubted value. It is employed as follows: The patient is placed in a room made absolutely dark and a small Edison incandescent lamp of about four candle power, which has been connected with a battery and fastened on the upper surface of a tongue depressor, is put in the mouth. The lips are now closed and the current of electricity turned on, so that the lamp may glow to its full intensity, whereupon the bones of the face will become beautifully illuminated, a darker shade marking the situation of the antrum. Should there be fluid or a

tumor within the cavity, the fact will become apparent by total absence of the illumination, and the marked contrast with the healthy side.

The water rheostat made by McIntosh & Co., of this city, or a thirty-two-candle incandescent lamp, used in the circuit with the Edison current, has enabled me to carry on my experiments satisfactorily.

A more simple test, and one upon which full reliance can be placed, is made with the peroxide of hydrogen used as follows: Cocaine having been freely applied to the middle turbinated body and the mucous membrane of the nasal cavity until thoroughly anæsthetized and contracted, a small hypodermic syringe, with a long cannula bent within a quarter of an inch of the distal end to a right angle, is passed into the hiatus semilunaris and a solution of peroxide of hydrogen (one part to twelve parts of water) is injected into the antrum. If pus be present, it is driven out and fills the nose as a white foam. That the solution has entered the antrum will be made evident by the patient complaining of slight pain at the roots of the teeth and a sense of fullness in the cheek. I know of no test so simple, free from danger, and easy of application, and yet so unfailing as this. By its means I have been enabled to diagnose empyema of the antrum where the only symptom was a slight discharge of pus in the nasal passage. In one instance, where the antra were pronounced healthy by a consulting surgeon, a subsequent operation confirmed the opinion of suppuration I had been induced to hold after the application of this test.

By the proper use of the peroxide of hydrogen one can satisfactorily differentiate between purulency of the maxillary sinus and the other hidden sources of pus which is discharged into the nose. Should the ostium maxillare be occluded and we be unable to inject the antrum, the symptoms of distension would soon set in and give undoubted evidence of that condition.

If it be deemed necessary to make an exploratory puncture, the difficulties which may arise from the plugging of the cannula, the thick bone, the abnormal conditions of the inferior turbinated body, the different positions of the antrum, and the danger of breaking the instrument, will cause one to hesitate before attempting it in the inferior meatus through the nasal wall, and to give preference to perforating the facial wall above the alveolus with a small drill.

Treatment can occasionally, particularly in acute cases from coryza, be advantageously carried out through the natural nasal opening by means of the cannula spoken of under the head of diagnosis, using diluted peroxide of hydrogen in preference to other remedies. But a majority of the cases will require surgical treatment in order to evacuate the antrum and give it free drainage. Much has been written in late years as to the best method of accomplishing this.

Mickulitz recently revived the practice of entering the antrum through the nasal wall, but the operation, for obvious reasons, seems destined to again become obsolete.

The operation which to-day stands in greatest favor among both dentists and surgeons, and which I shall presume to discourage, is that of entering the antrum through the alveolus. Regarding it, Voltolini, quoting Walb,* advises the opening to be made through the alveolus, and considers this situation of such importance as to advise the pulling of even a sound tooth in order to carry out this recommendation. Bosworth † advises that the artificial opening be made in the same situation.

Dr. W. Carr, ‡ of New York, says: "I should never hesitate to make the opening through the alveolus even at the sacrifice of a sound tooth."

Dr. J. H. Bryan # is equally explicit: "The operation that has met with the most favor is that known as Corper's—viz., through the alveolar process. In case a molar tooth is present, it should be extracted and the opening enlarged."

Garretson ‖ says: "The second molar tooth is to be extracted and penetration of the cavity effected through the alveolus of the palatine fang."

After such evidence in favor of the operation through the alveolus and without reference to other authority, we should seriously consider the question as to the most advisable position for the opening to be made into the antrum before we condemn that which has the support of men of experience and which has endured the test of time, and offer in its stead an operation which, to say the most of it, has but the result of a few cases in evidence of its claims for superiority.

The prime object of opening the antrum is to give it free drainage and to enable us to medicate its diseased mucous membrane. The latter of these indications is easy to accomplish, and the former only requires that the aperture be made in the most dependent portion of the sinus; but does drilling through the alveolus from below upward always secure this? Anatomists agree that there are several conical processes projecting into the antrum corresponding to the first and second molar teeth, one of which is generally sacrificed in the operation. When the tooth is removed the projection remains in the floor of the antrum, and if we penetrate the thin plate forming it and enlarge the opening, as is advised by writers on the subject, the base of the elevation remains and offers an obstruction equal to its height to the complete and thorough drainage of the antrum. This objection may be considered chimerical, yet we are justified in assuming it to be one which may exist if we hold the statements and drawings of anatomists correct, and as yet we have no reason to doubt them.

This may possibly have been the cause of failure to check the formation of pus in some cases reported in medical literature.

A plug retained in the artificial opening will maintain its patulency and exclude foreign matter, but it will also

‖ *A System of Oral Surgery*, p. 757.

interfere with complete drainage. It, however, will serve to bring about good results if the case has not been one of long duration. A tube of metal will be required in the more chronic cases, but the use of this when placed through the alveolus from below is an annoyance to the patient, and he may fail in his endeavors to keep foreign matter from entering it.

Modern dental surgery has taught us to value a dead tooth, and even a root, provided it is not causing irritation, and hence it appears to be our duty not to lightly sacrifice them for any purpose when the same end can be accomplished by other means.

The operation which I prefer is that of opening the antrum in its most dependent portion, but through the upper part of or immediately above the alveolus, as follows: The mucous membrane having been locally anæsthetized, an incision is made into it or a small piece is cut out with a tubular knife just below the gingivo-labial fold between the upper portions of the roots of the second bicuspid and first molar teeth. A drill, preferably driven by an electric motor, is entered at the point of incision into the soft tissues and directed upward, inward, and slightly backward, forming an angle of about forty-five degrees with the plane of the alveolus. A few revolutions will send the drill into the antrum at its most dependent portion. The opening thus made must be of sufficient diameter to admit of thorough cleansing and draining. A gold tube is to be well fitted so that the distal end will enter just within the antrum, and to the other end projecting beyond the mucous membrane a small strip of gold is attached and fastened to a collar around the tooth. By this method we have free drainage without the danger of foreign substances entering the antrum, and plugging the tube is not necessary. I find that cases so treated have invariably done better than those where the opening had been made through the alveolus from below, and, as the operation is free from any of the objections made to the latter, I urge its trial and condemn the extraction of a sound or even of a diseased tooth for the purpose of entering the antrum.

The after-treatment consists in daily or twice a day washing the cavity with a saturated solution of boric acid and occasionally injecting iodine, sulphate of zinc, or subnitrate of bismuth.

A summary of the nineteen cases which have come under my observation during the past eighteen months shows, of twenty-one suppurating antra, that nine were due to "catching cold," eight were due to dental complications, one was due to polypi of the antrum; two, cause doubtful, and one, unknown cause. Fifteen were diagnosticated by the assistance of peroxide of hydrogen. Three were cured, and one is now under treatment by medication through the natural nasal opening. In ten the antra were opened through the upper part of the alveolus below the gingivo-labial fold. In two a tooth was first extracted, and in four a tooth had been extracted at a prior date and the opening made through the alveolus from below. One patient refused treatment; one is now under treatment.

126 State Street.

INJURIES OF THE HIP AND ABSORPTION OF THE NECK OF THE FEMUR.*

By REUBEN A. VANCE, M. D.,
CONSULTING SURGEON, SAINT ALEXIS HOSPITAL, CLEVELAND, OHIO.

The injuries of the hip that result in fracture are well known; the fractures thus produced in their various aspects have been so much discussed and written about that their literature is one of the most voluminous in the history of practical surgery. On the present occasion I wish to call your attention to one of the consequences of injuries of the hip that has been but little discussed or written about, and which is nevertheless one that has exercised an unrecognized but potent influence over the progress of all lesions about the head and neck of the femur. I refer to absorption of the bony tissues of the femoral cervix, the result of injuries—a lesion not necessarily preceded by fracture, but one that may occur as a consequence of contusions of the hip.

That this lesion has been recognized is well known to all familiar with the writings of Benjamin Bell and George Gulliver. Within recent years Richard Quain, in his *Clinical Lectures*, has set forth this peculiar consequence of injuries of the hip in a lucid manner, and illustrated its morbid anatomy with great success.

A brief review of two of the earlier cases will fitly introduce what I shall have to say on the subject. The first case is from the *Edinburgh Medical and Surgical Journal*, No. 128, for July, 1836; the second from the same periodical, No. 129, for October, 1836; both are contributed by Mr. George Gulliver, and, in the number last named, the morbid appearances are illustrated in excellent style.

"J. Fox, aged thirty-two, after a service of eight years in the West Indies, died of phthisis, for which disease he had been two years under treatment in hospital. A long time after his confinement it was noticed that his right inferior extremity was emaciated, but there was no note of any affection of the limb previous to his admission into hospital. At the post-mortem the right inferior extremity was found by measurement to be at least an inch and a half shorter than the other, and the extent between the pubis and trochanter of the affected side was diminished in a corresponding manner. The limb was much emaciated, but its position was natural, and the motions of the coxofemoral articulation were not impaired. Having removed the upper part of the femur, I found the neck absent. The head was flattened and expanded considerably; it was approximated to the shaft, so as to be situated much below the great trochanter. A section of the part was made, when the upper and lower shell of what remained of the neck was seen to be formed of compact bone, quite equal to the ordinary thickness in this situation, and the reticular texture of the bone was more dense for some distance from the edges, so as to form an indistinct line on either side of the most contracted part toward the center. The cancelli were filled with caseous matter, in some places nearly colorless, in others tinged with dark grumous blood. The acetabulum was diminished in depth, but enlarged laterally, so as to correspond with the altered shape of the head of the thigh bone. The cartilage of the articulation presented throughout its usual thickness and consistency, and was gener-

* Read before the Society of the Alumni of Bellevue Hospital at its first annual reunion.

ally smooth and lubricated with synovia. I examined the other thigh bone and found its form and condition in every respect natural. I now sought information concerning the history of the case from some of Fox's comrades, who had served and come home with him. From them it appeared that Fox had received a fall about three years before in the Island of Nevis, in consequence of which he often complained of pain about the hip, but continued to do his military duty many months after, never having been confined on account of the accident. The morbid parts described in this case are preserved in the Museum of the Army Medical Department."

"John Lynn, aged nineteen, a stout, active recruit of the Thirty-eighth Regiment, fell into the hold of the ship in which he was proceeding to join his corps in India, and injured the right hip, in consequence of which he was confined to his berth. On his arrival in India, about three months after the accident, being perfectly well, he was attached to the light company of his regiment. He continued to perform the active duties required of him in this company for about three years after the accident, when he became very gradually lame in the injured limb and was accordingly admitted into the hospital. When he had been about eighteen months under treatment, the infirmity increasing, he was considered to be unfit for service. His general health had been throughout good, and he was accustomed to move about with the assistance of a crutch, but he was so much addicted to the drinking of ardent spirits that it was deemed expedient to retain him in hospital until he could be brought before the annual invaliding committee. While detained for this purpose he was bit during the night by a snake (*Bungarus lineatus*), from the effects of which he died in a few hours, being then twenty-four years of age.

"The hip joint presented to the Museum of the Army Medical Department, by Dr. Dempster, exhibits remarkable shortening of the neck and enlargement of the head of the thigh bone, with suitable change of form in the acetabulum. The head of the bone is enlarged principally around its inferior border as if from expansion, its upper and front part being flattened, so that the articular surface extends anteriorly close to the shaft, while the neck presents a greater extent posteriorly. The acetabulum is much widened and remarkably shallow, corresponding to the alteration of shape in the head of the bone. A section made in the usual direction through the upper part of the thigh bone exhibits the center of its neck hardly half an inch long. There is no appreciable diminution in the density or strength of the bone; and the compact shell of the neck, as well as the cancellous structure, appears throughout perfectly natural. The articular cartilages, as far as can be ascertained from a dry but imperfectly macerated preparation, appear of the usual thickness, without a trace of ulceration."

I will now recite certain facts in the history of a case that has long been under my observation:

A gentleman, forty-seven years of age, a native of Ohio and a life-long resident of Cleveland, while on his way to his place of business in December, 1886, slipped and fell, striking on the right hip with sufficient violence to make a decided ecchymosis over the trochanter major. Although suffering much pain, he continued his journey and attended to his usual vocations. The only change he felt compelled to make was to ride to and from his place of business during the ensuing week. The limb was sore and weak during this interval, and over the bruised region felt very tender. At the end of that time he was awakened one night by violent pain in the knee; this was so severe that he remained in bed the following day. The next morning he was able to go to his store as usual, and since then has not lost an hour from business on account of pain in or defect of the limb. In May, 1887, he noticed that he was wearing off the back of the right pantaloon leg, and became conscious of a slight halt in his gait. He then fell under my observation. In answer to my inquiry, he said that every night the leg was weak and a trifle painful, that before the injury there was never the slightest defect in his limbs. In May, 1887, careful measurements revealed between half an inch and an inch shortening; the right thigh was three quarters of an inch less in circumference than the left. No difference was perceptible in measurements between the top of the trochanter major and the lower end of the femur on the right and left side; or, with the limbs extended, between the trochanter major and the malleolus of the fibula on either side. But there was a decided difference on the two sides when measurement was made between the crest of the ilium and the trochanter—and the whole of the shortening on the right side could be accounted for by the approximation of the right trochanter to the iliac crest. At this time the motions of the hip joint were unimpaired, and no tenderness was apparent when the joint surfaces were forcibly approximated in different positions of the limb. The range of motion of the thigh was limited in but one direction—the limb could not be abducted to the same extent as the left. There was no eversion of the right foot. He called for an opinion as to the nature of his injury and its future progress, he then contemplating a suit for damages against the property owner in front of whose premises he fell—a suit that was never brought, owing to advice received from counsel.

This gentleman has been under my observation ever since. I have recently repeated my examination, and his present condition is as follows: There is an inch and a quarter difference in the circumference of the two thighs; an inch and a half in the length of the two limbs, located in the upper end of the right femur. The motions of the thigh are now restricted in every direction, particularly so in abduction. Within a circumscribed limit, however, he can flex, extend, abduct, adduct, and circumduct the limb as well as ever. With the limb straight he can neither invert nor evert it to the same extent as its fellow, and when lying on his back the right foot seems somewhat everted. After exertion there is a sense of weakness in the limb, and at all times a decided halt in his gait, but he is free from pain and can walk to and from his place of business without distress. In short, he is weak and lame in the right lower extremity, but otherwise well.

Quain admirably summarizes the morbid anatomy of this lesion. The changes involve the neck and head of the femur and acetabulum of the pelvic bone, and are indicated by comparison with the bones of the opposite side in their natural state. The head of the femur is expanded and flattened, and shortened as if thrust down. The regular arrangement of the arches of the cancellated structure is no longer apparent, the joint surfaces are not inflamed, the cartilaginous investments are intact, and the peculiar lesions of chronic rheumatic arthritis are absent.

In the *American Journal of the Medical Sciences* for October, 1867, will be found an extremely interesting article by Dr. John H. Packard, of Philadelphia—On Some Points relating to Fractures of the Neck of the Femur—in which are adduced many considerations that bear forcibly on any conclusions that may be drawn from the clinical

and pathological facts above set forth. But my object at present is not so much to dwell upon those aspects of the case as to emphasize certain medico-legal features that are liable at any moment to assume prominence. These are of especial interest to the medical profession. Some years since a prominent surgeon in Cincinnati was hailed while driving along the street by a young physician, who requested him to stop and glance at a painter, who, in falling from a ladder, had dislocated his thigh, which dislocation the young man assured him he had reduced. The surgeon complied, saw the patient, examined the limb, and assured the injured man that the thigh bone was back in its proper position. This was all the professional connection the surgeon had with the case. It seems that in a couple of months the painter was back at his business apparently all right, but in a few weeks he began to walk lame, and at the expiration of another month or so his legal representative called on the surgeon with a demand for compensation, alleging that, through want of skill on his part, a fracture of the neck of the thigh bone had been overlooked, and that his client was lame as a result of such malpractice. In this position, the lawyer went on to say, he was sustained by the opinion of a local professor of surgery and practitioner of high repute, who had assured him that the lameness of his client was wholly due to failure on the part of his surgical advisers to resort to measures calculated to keep the parts at rest until the fracture of the neck of the femur had united; that, by permitting him to get up too soon, either the callus had yielded or the hitherto untorn portion of the cervical ligament had ruptured; and that the shortening of the limb of late development was due to one or other of these causes, and could be due to nothing else. This case, vexatious and expensive as all such cases are, finally came to naught from inability on the part of the painter to stand the expense of litigation, and not because of the injustice of his claim or the bad character of the surgical advice on which it was based.

In the interpretation of these cases during life a history of the patient is of the utmost importance. Absorption of the neck of the femur may follow the most diverse injuries. If there has been fracture or dislocation, the surgeon will always guard his prognosis; it is in the slighter cases, and those where a simple contusion alone is apparent, that trouble is apt to arise; conversely, in patients where an injury of the hip is not attended by inability to walk that lasts for weeks; where no shortening occurs at first, but is of late development and gradual onset; where the defect in length is shown not to be located in any other part of the limb than the region around the joint, and where other parts of the body are free from evidences of chronic rheumatic arthritis, the morbid anatomical condition is absorption of the neck of the femur.

The late Dr. W. T. O'Donnell.—Dr. O'Donnell, of Devil's Lake, North Dakota, died on the 2d of May, at the age of forty-seven. He was a native of New Hampshire and a graduate of Dartmouth College. Dr. O'Donnell was an excellent classical scholar and a devoted student of Hippocrates and other ancient medical writers, and several communications of his relating to their writings have appeared in this Journal.

ACUTE PRIMARY BRONCHO-PNEUMONIA,

WITH LOW TEMPERATURE AND OTHER OBSCURE SYMPTOMS.*

By L. EMMETT HOLT, M. D.,

PROFESSOR OF DISEASES OF CHILDREN IN THE NEW YORK POLYCLINIC.

The diagnosis of acute disease among infants of the first few months of life is attended by peculiar difficulties. This difficulty depends not so much upon the fact that a wide range of diseases is likely to be met with as it does upon the masking of the ordinary diseases by very unusual symptoms. If one has the opportunity to see the autopsies in his cases, he is continually surprised at the want of correspondence existing between the symptoms and the lesions.

The following two cases of broncho-pneumonia illustrate this point; in both cases almost all the usual symptoms of pneumonia were wanting, and yet the lesions were typical.

Case I. *Extensive Broncho-pneumonia in the Upper and Lower Lobes of the Right Lung; Mild Gastro-enteric Symptoms for Four or Five Days; Pulmonary Symptoms only Twenty-four hours, and these Obscure Ones.*—A fairly nourished female infant, five weeks old, was admitted to the Babies' Hospital, February 11, 1890. It was sent from one of the day nurseries, where the child had been under the daily observation of a physician. For four or five days the movements from the bowels had been green but not very frequent, and there had been occasional vomiting. The symptoms were attributed to improper feeding.

When admitted, the child seemed bright; cough was not noticeable; there was no vomiting; the passages were very green and contained undigested food, but were not frequent or offensive. The evening temperature was 101° F. A teaspoonful of castor-oil was given and a comfortable night passed. Four green movements in the first twenty-four hours. On the following morning three drops of paregoric were given. Within a few hours after this dose the appearance of the child changed completely. The pulse became weak and thready; there was considerable dyspnœa, the respirations being rapid and superficial, with a peculiar catch in the middle of each inspiration, so that this appeared double, while expiration was natural. There was slight general cyanosis; the pupils were tightly contracted, the eyes a little sunken, the fontanel depressed, the face drawn and anxious; there was general relaxation, and the whole aspect of the case was alarming in the extreme. A careful examination of the chest was made, but only rude breathing sounds could be heard anywhere, of about equal intensity upon the two sides. The rectal temperature was 99° F. throughout the entire day.

Mustard packs and hot baths were used at short intervals and stimulants by the mouth freely given, and, though at first some reaction was produced, the child lost ground steadily during the day. By evening there was marked cyanosis, cold extremities, pulse too rapid to be counted. Death occurred during the night in a condition of collapse, the infant having had severe symptoms less than twenty-four hours.

Autopsy.—Thirty hours after death. Brain not examined. Lungs show no fluid in either pleural cavity. The left lung normal, slightly congested behind. One third of the right upper lobe and about three quarters of the lower lobe behind were consolidated, dark-colored, slightly mottled with gray; no crepitation, the condition shading over gradually into the healthy lung. On section, fairly typical broncho-pneumonia. Slight

* Read before the Section in Pædiatrics of the New York Academy of Medicine, April 10, 1890.

swelling of the bronchial glands. Right auricle and ventricle contained dark fluid; a small, partly decolorized thrombus in the right ventricle extending into the pulmonary artery. Foramen ovale closed excepting a pin-hole opening; the kidneys were pale, but the organs essentially normal, including the intestines.

I made a microscopical examination of the lungs in this case to clear up any lurking suspicion in the mind of any one that this was not a case of pneumonia at all, but only collapse.

There was, as in the next case, in all the consolidated areas, a very extensive exudation of round cells filling the alveoli, especially about the larger blood-vessels and the bronchi, and, in addition, in many places quite large capillary hæmorrhages.

Case II. *Acute Broncho-pneumonia, Cardiac and Pulmonary Thrombi, and Areas of Pulmonary Gangrene; Severe Symptoms only Two Days; Low Temperature.*—A well-nourished male infant, six months old, was admitted to the Babies' Hospital on the evening of Monday, February 17th, with general symptoms of great prostration. The pulse was 120, but weak and intermittent; respirations, 32 and quite labored; temperature, 101·4°. The child was drowsy and swallowed with difficulty; slight cervical opisthotonus; pupils normal; no bulging of fontanel.

This child was also sent from a day nursery, and the following history was obtained: Well till one week ago; since then a slight cough; two days ago bowels loose, but no passage for past twenty-four hours; right ear discharging for two days. The infant had been at the day nursery on the Saturday previous; was seen at that time by the physician in attendance, and did not seem at all sick. On Monday for the first time did the child appear ill, and when it was brought back to the nursery the mother was directed to the hospital. A hot mustard bath and free stimulation ordered.

On the following morning the temperature was 99°; pulse, 132; respirations, 44. The prostration had increased, there was no stupor, but the infant was very drowsy and quite relaxed: there was pallor, but no cyanosis; fontanel depressed; marked recession of epigastrium and suprasternal and supraclavicular spaces on inspiration; no dullness; very rude respiratory murmur over the whole chest, with only a few coarse râles at the bases of the lungs. The respirations were so shallow and superficial that the examination was not very satisfactory. Throat negative: opisthotonus still present. As there seemed no evident cause for the prostration and drowsiness, the intestines were irrigated and the stomach washed out without any apparent improvement in the condition. No urine was passed during the day. By evening there was a very decided increase in all the severe symptoms, the prostration extreme, bordering on collapse in spite of stimulants both to the skin and internally.

At 7 P. M. the temperature was 96°; pulse, 140 and very weak; respirations, 48, with great dyspnœa; slight cyanosis.

He now passed into collapse and died at 3 A. M. the following morning, thirty hours after admission and forty-eight after the onset of severe symptoms.

Autopsy.—Eleven hours after death. Slight congestion of the brain; otherwise normal.

Lungs.—No fluid in the pleural cavity. Slight fibrinous exudation of recent origin upon the posterior surface of both lower lobes. The right lung showed partial consolidation of the posterior and upper portion of the upper lobe, very extensive consolidation of the lower lobe, the anterior portions of both being congested and œdematous. On section, these portions gave the typical appearances of broncho-pneumonia. Near the center of the lower lobe was a grayish area, in which the lung tissue was almost completely disintegrated. It was gangrenous, but without any odor. The gangrenous area was about the size of a walnut; in the artery leading to this area a firm thrombus, completely filling it, was found. In the central part of the right middle lobe there was a similar gangrenous area and a similar thrombus. These thrombi extended to the large branches of the pulmonary artery at the root of the lung. The left lung showed typical broncho-pneumonia in the posterior portion of both lobes, the lesion not quite so far advanced as upon the right side. At the root of the left lung a cheesy bronchial gland was discovered, and quite near it a very small area, in which were scattered recent miliary tubercles. On section of this, a small, cheesy nodule the size of a pea was found. The bronchial glands at the root of the right lung were swollen but not cheesy. No tubercles were found in any other part of the body.

The heart contained a small thrombus in the left ventricle, which extended slightly into the aorta and also into the left auricle, being closely adherent to the mitral valve. In the right ventricle there was a much larger thrombus, extending some distance in the pulmonary artery. This also extended into the right auricle, to the walls in which it was very closely adherent. There was quite marked cloudy swelling of the kidney, but the other organs were essentially normal. The appearance of the tubercles in the lung is evidently only an incident in the case, as this certainly had nothing to do with the symptoms and was entirely distinct from the pathological process in the lungs elsewhere. It is, however, of interest as showing a tubercular affection of the lung from a bronchial gland pretty clearly occurring in the child under circumstances when it would be scarcely expected and evidently having caused no symptoms, although the process must have existed for some time.

Microscopical examinations were made of several parts of the lungs and of the kidney by Dr. R. G. Freeman. Ordinary typical broncho-pneumonia was found with very abundant exudation of cells into the alveoli, but little fibrin. The epithelium of the convoluted tubes was quite granular, and in a few places cast matter was found in the tubes.

Remarks.—In both these cases the lesions were very ordinary ones, with the exception of the thrombi and gangrenous areas in the second child, and yet the history, the symptoms, and the course are as far as possible from those seen in typical cases of pneumonia.

In both cases the lesion was evidently very recent, but certainly in the second child considerably longer than the two days of acute symptoms. There was then in both cases acute pneumonia with early latent symptoms.

The low range of temperature is a point of especial interest. While it is very common for secondary pneumonia to develop with little or no elevation of temperature, it is very exceptional to see so little fever in cases of acute primary pneumonia. On the contrary, high temperature in a case of acute illness is generally the thing which makes us scrutinize the lungs for evidence of disease.

In Case I a singular feature is the fact that severe symptoms first developed shortly after a dose of opium, although this was a small one—only three drops of paregoric. The embarrassed respiration, slight cyanosis, and contracted pupils suggested strongly opium poisoning. Without the autopsy there would have been certainly some good reasons for believing that the opium had had something to do with

the infant's death. In the light of the lesions found, the connection can not be regarded as anything more than a coincidence.

In Case II the pathological conditions considered in relation to the symptoms were: (1) Cerebral congestion or possibly meningitis associated with the otitis; (2) toxic symptoms from gastro-enteric catarrh; (3) acute nephritis and uræmia; (4) acute pulmonary congestion with areas of collapse; (5) pneumonia.

Pneumonia was strongly suspected in this case from its resemblance to Case I, the autopsy upon which had been but a few days before.

We are, then, to suspect pneumonia in infancy if dyspnœa, rapid breathing, great prostration, and slight cyanosis exist, even though the temperature be scarcely above the normal and though the examination of the chest may give no positive evidence that the lungs are diseased.

The great frequency of pneumonia in young children should put us always on our guard to watch for its many masked forms.

15 East Fifty-fourth Street.

AN INTRALIGAMENTARY OVARIAN CYST

SUCCESSFULLY TREATED WITH IODINE INJECTIONS.*

By R. B. RHETT, Jr., M. D.,
CHARLESTON, S. C.

On April 7, 1889, I was called to Mrs. H., white, aged twenty-eight, who gave the following history: She had always suffered some dysmenorrhœa, except from August, 1886, when she had an attack of typhoid fever, to October 10, 1887, when she married. During that interval there was no pain or difficulty. For years she has suffered slightly from incontinence of urine. Immediately subsequent to marriage the dysmenorrhœa returned and increased in severity; the pains, dragging weights, etc., continued also between the periods. She felt sick and badly all the time, but believed this to be the normal condition of women during early married life. In January, 1889, she missed her periods. In February for the first time she noticed in dressing that her abdomen had become enlarged, as her clothes were too tight, and thought she had conceived. On February 20th her menses returned and continued almost constantly until April 1st, when her physician prescribed medicine which stopped them. On March 8th she was seized suddenly with most violent cramps and retching. The agony was so intense that she fainted four or five times. She was also unable to void her urine, though constantly attempting to. Her family physician drew off her urine repeatedly and administered anodynes. On the 18th, while she was still confined to her chamber, another attack occurred similar in every particular, though slightly less in intensity. For some months she had suffered from constipation and there seemed to be some obstruction in the passage.

In 1886 she fell down a flight of stairs. For some time previous to March 8th she was in the daily habit of lifting buckets of water through a window. In raising the buckets from the outside piazza floor the abdomen was strained against the window-sill and often caused sharp pains. This fall or the forcible compression of the abdomen against the sharp edge of the sill may account, by having caused hæmorrhage, for the color of the fluid in the tumor, which at the operation was found to be brown.

* Read before the Medical Society of South Carolina, April 23, 1890.

Physical examination revealed the presence of a tumor extending across and occupying the lower part of the abdomen from the right inguinal region just below the anterior superior spine of the ilium to just under the left twelfth rib. The tumor was hard and tense and felt like a fibro-cyst. It could be felt plainly pressing down on the anterior wall of the vagina, and there gave the sensation of a solid growth.

The womb was fixed and deflected to the right, and measured four inches and a half in diameter. The bladder was elongated.

An effort, with partial success, was made to improve the patient's general condition before operating, by means of baths, tonics, etc.

About the middle of April Dr. J. J. Edwards was called into consultation and agreed with me as to the propriety of operating for the removal of the growth.

The diagnosis of an intraligamentary ovarian cyst was made, and measures for operating were taken accordingly.

On May 1, 1889, the operation was performed. An incision about four inches in length was made in the median line, reaching to about two inches below the umbilicus and just below the upper margin of the tumor. The incision was very cautiously deepened until the cyst-wall was reached and recognized. A trocar resembling Dunster's was thrust in near the upper extremity of the incision and the sac partly evacuated of a brown fluid. The opening was then carefully prolonged through the cyst-wall downward. The patient was then turned on her side and the fluid and solid contents of the sac were scooped out with the hand and the cavity was thoroughly washed. She was then turned back and the incision carried up into the peritoneal cavity. A short coil of intestines was found adherent to the peritoneal surface of the tumor and was released. Later during the operation this raw oozing surface of the coil bulged up into the opening and, in checking hæmorrhage, was grasped with pressure-forceps by an assistant and so bruised by the forceps as to necessitate the sewing up of about an inch of its surface.

An attempt was made to peel out the tumor; but the hæmorrhage was so terribly profuse and the constant necessity of stopping to control it so great, that very little progress was made. The patient was several times during the operation injected hypodermically with ammonia and hot bottles were kept in constant contact with her person. She became so weak that death on the table was imminent, and I decided to abandon further efforts to enucleate. The abdominal and tumor cavities were thoroughly cleansed with hot water. The edges of the incised peritonæum were sewed together, closing off the peritoneal cavity completely from that of the tumor. The freed portion of the sac, which in proportion to what remained was very little indeed, was cut off and the edges were drawn in apposition with sutures. The wound of the abdominal walls was closed by deep stitches with two drainage-tubes in the lower angle—one glass, bent at an angle, passing into the pelvic cavity and the other, of rubber, seven inches long, pushed into the upper portion of the sac.

The cavity after the first twenty-four hours, for two weeks, was injected every four hours with bichloride-of-mercury solution, 1 to 10,000 of boiled water, and once daily with about half an ounce of tincture of iodine, containing a small quantity of saturated solution of iodide of potassium to prevent the iodine from being precipitated when coming in contact with any water remaining in the cavity that had just previously been washed out. The iodine was thrown through a long-nozzled syringe against the upper surfaces and into the two sulci—one of which was under the left twelfth rib and the other in the right inguinal region. Three hours after each of these injections the sac was washed out. The syringe used

while the tracts were large enough was one with a bent nozzle, which Emmet recommends for withdrawing mucous discharges from the uterine canal.

When the tracts became too small a malleable silver cannula attached to a small aspirating syringe was used. For the first two days a few drops of carbolic acid were added to the tincture of iodine, with the idea of producing a slight caustic action. I now, however, believe that the quantity was so small that it had no effect. At no time did the patient complain of much pain deep in the abdomen. The opening and the surface around it were greased with vaseline. As the cavities contracted the tubes were removed, one at the end of three weeks and the other at the end of five. The injections of iodine after the second week were for a short time given every second day, and then every third until the tenth week, when the cavities had entirely closed. After the third week the iodine was immediately withdrawn with the injecting syringe, as it was believed that the surfaces were all thoroughly reached, and the tracts were not washed out in three hours. After the eighteenth day the discharge changed and became a transparent amber-colored fluid. At the end of six weeks the patient was up, and has since enjoyed excellent health, and there is at present no evidence whatsoever of any return of the growth.

I have searched the limited literature within my reach and find no reference to a similar line of treatment. The old treatment of injecting any ovarian cyst cavity after tapping, where the products of inflammation were locked up in the cavity, I regard as different in material points. The theory upon which this treatment was based was, that, because of the low vitality and non-malignancy of the structures, besides its antiseptic and hæmostatic effects, the pure tincture of iodine might, as it does in some pathological conditions of the endometrium, produce disintegration, resolution, and complete absorption of the growth. This effect followed in this instance, but there may have been other factors which accomplished the result. The test of experience alone can prove it. But if time should establish it to be the best and safest treatment, then should we have a simple and easy process substituted for one from which even the boldest and most skillful gynæcologists shrink.

The appalling hæmorrhage, the dangers of tearing the ureters, the rectum, the bladder, etc., would be entirely removed, and in many cases it would be unnecessary to even open the peritoneal cavity.

A CASE OF PERSISTENT VOMITING, WITH A HISTORY OF CHYLOUS (?) VOMITING, RELIEVED BY LAPAROTOMY.*

By A. H. BUCKMASTER, M. D.

Mrs. C., aged thirty-five, married fourteen years, and the mother of one child, sought my aid for the relief of persistent vomiting. She had had no miscarriages, and her only labor was a severe one. The membranes ruptured at 2 o'clock A. M., and the child's head appeared at the vulval cleft at 2 o'clock P. M., where it remained until 6 o'clock, when delivery took place spontaneously. There was a complete rupture through the recto-vaginal septum. Seven days after labor, while nursing the child, as the patient felt the distention in the breasts, she regurgitated a milky-white fluid through the mouth. This happened every time she nursed the child, and finally led the medical attendant to advise the weaning of the infant, which was done. She drank no milk after the birth of the child, taking cocoa, gruel, etc. As the milk decreased, *pari passu* the amount of regurgitation of milky fluid also diminished.

Seven months later Dr. W. G. Hoyt, of this city, restored the recto-vaginal septum.

A year and a half after the labor the patient began to vomit daily. She consulted Dr. Stern, of Leicester, Mass., who treated her during the summer, with slight improvement of the symptom. The vomiting occurred immediately after eating, and at other times irrespective of the taking of food.

The patient then came to New York and saw Dr. Weinberg, and was by him referred to the late Dr. James B. Hunter. Dr. Hunter placed her in the Woman's Hospital, and thought the trouble was due to enlarged and cystic ovaries, and recommended oophorectomy. The patient was so weak at the time that her friends decided not to have her undergo the operation. She went to Brooklyn and entered the Long Island College Hospital. She remained a short time, and finally consulted me, by the advice of Dr. Thomas B. Watkins, now of Chicago. I found her much emaciated and so weak that she could scarcely walk. On either side of the uterus were two large, movable masses, of about the size of small lemons. She complained that she could not drink part of a glass of water without vomiting. Examination of the urine revealed nothing, and I sent the patient to Dr. B. F. Westbrook, of Brooklyn, asking him to go over the case carefully for any organic disease that might account for the vomiting, and to state whether he considered the vomiting of a reflex character, and if the patient could stand the etherization. Dr. Westbrook returned a written report, advising the removal of the masses in the pelvis, as he could find no other cause for the vomiting, and stating that he considered the patient's condition critical. In January, 1889, I removed the masses spoken of, which were very much enlarged ovaries. There were no adhesions, and the patient made an uninterrupted recovery. She did not vomit after the operation, except when coming out of the anæsthesia, for four months, and gained in flesh during this time thirty-six pounds. At the end of this period vomiting began again and soon was as bad as ever. After drifting from physician to physician, she sought my care in the following September. I again used all the means I could think of to help the trouble, but without avail. Lavage and strict diet of various kinds proved futile. The cervix contained a slight amount of hard tissue. This was removed with no favorable result.

On December 7th I made an explorative incision, thinking perhaps that Loreta's operation might be indicated. I removed the small intestines from the abdominal cavity and carefully examined them coil by coil for adhesions or other abnormities. The pyloric orifice was palpated, as were the kidneys. The only thing noticed was that the right kidney appeared somewhat enlarged, and just above it was what I took to be an enlarged suprarenal capsule. The abdomen was closed, and the patient did not vomit for several months. It is now five months since the last operation, and the patient states that vomiting has begun again, and she fears that she will be as bad as ever.

The two interesting points in the above-given history are the temporary cessation of the vomiting after laparotomy and the milk-like vomiting after the birth of the child. The latter symptom, which I had on the statement of the

* Read before the Alumni Association of the Woman's Hospital, January 16, 1890.

patient, I treated as an idle story until by repeated cross-examination of the patient's mother and husband I was unable to make them contradict the assertion. Dr. Busey's interesting article on The Effusion of Chyle and Chyle-like, Milky, Fatty, and Oily Fluids into the Serous Cavities* has induced me to present this case for your attention, and in closing I will take the liberty of quoting two of his foot-notes:

"Practicus observed saliva evidently milky. For a woman, he says, nursing a child, again became pregnant, and therefore weaned the child. The right breast, from neglect, became like a large tumor, and on a certain night subsequently, while suffering much pain, she had an abundant discharge of milk from the mouth, with a corresponding decrease of the swelling in her breast. She swallowed the milk as it came into her mouth (without any inconvenience), which continued for four months.

"But it may be asked, How came the decrease in the breast? In my judgment, in no other way than this: that the masses of the blood were laden with chyle, the particles of which could not permeate the lactiferous tubules of the mammæ on account of their collapsed condition, but formed a tumor in those nearest the mammary gland, especially since their arteries were filled and were not capable of removing any more. Indeed, the chylous and milky particles were abundantly distributed through the blood mass, and permeated the glandular structures, especially the salivary, which offered the least resistance. In the mean time the blood, on account of its freer and quieter motion, propelled the chylous particles remaining in the breast toward the veins, and thus to the heart; hence it followed the breast was emptied." *Sialographia, etc., Ductuum Aquosorum Anat. Nova.* Lugduni Batavorum, 1695, p. 49.

"A woman who was nursing twins began to complain, a few days after the death of one of them, of a sense of dull pain and tension beneath the ribs of the right side of the abdomen and over the umbilicus. This feeling was succeeded by stretching, the stretching by itching, and the itching by an exudation of fluid from the skin, the color, taste, and consistence of which were identical with milk, and which yielded a true butter on agitation." *Ephemerides Germaniæ*, decur. ii, ann. viii.

HYSTERECTOMY FOR ŒDEMATOUS FIBROID.

RECOVERY.

By RICHARD DOUGLAS, M. D.,

PROFESSOR OF GYNÆCOLOGY, MEDICAL DEPARTMENT, VANDERBILT UNIVERSITY, NASHVILLE, TENN.

Jane V., colored, aged forty, widow, of short and thick stature, the mother of three children, youngest eighteen years old. Five years ago she discovered a hard, round, painless tumor, about the size of a small orange, in the left inguinal region. There was but little change in the growth during the first two years of its recognized existence; during the last three, however, its growth has been quite active. Her menstrual history normal; slight vesical and rectal irritation, with a sense of weight and heaviness in pelvis, were the only symptoms indicating its presence, she being able to discharge her duties as cook in a private family up to January 1, 1889, since which time the growth has been rapid, the tumor attaining such dimensions as to give rise to serious symptoms, attributable to size and weight. When first seen by me in July last she was confined to her bed; the abdomen was greatly distended by a large, smooth, symmetrical, and decidedly elastic tumor. The poor woman was in great distress, unable to walk or stand with comfort; confined to her bed, finding rest only upon her side; in changing her position it was necessary for some one to assist in lifting the tumor over; at times there was alarming dyspnœa; obstinate constipation, and decided tenderness all over the tumor. Vaginal examination was negative, the uterus being almost out of reach high up in the pelvis. Operation was advised but refused.

On September 20th was recalled, and found her general condition much worse. The tumor was now hard, yet in parts there was a deceptive wave appreciable. The diagnosis was extremely difficult, but, from race, clinical history, and physical signs, it pointed to œdematous fibroid.

After due preparation she was submitted to operation on September 28th. The usual short incision was made, the character of the growth found to be soft fibroid, and its removal determined upon. The incision was extended as necessary to a point one inch below the ensiform cartilage; the growth almost filled the abdominal cavity; the greater omentum was spread out and attached over its entire anterior portion, and immense veins larger than a lead-pencil, a dozen or more in number, coursed over its surface; strong and vascular adhesions attached the tumor to the ascending and transverse colon, and a coil of small intestine was adherent to the left side. The adhesions were grasped with forceps and ligatured on the proximal side with No. 4 carbolized silk, and divided between forceps and ligature, the forceps being left *in situ* on the tumor side in preference to double ligature, simply as a matter of expediency. All the adhesions were carefully treated in this manner, and the tumor, freed of all save its deep pelvic attachments, was delivered from the cavity and held well up by the assistants. The appendages were so much elongated by the growth that they were with ease brought up alongside of the body of the uterus, and the wire, of Bantock's modification of Kœberlé's serre-nœud, was made to embrace the uterus and appendages just above the vaginal attachment. The clamp was now tightened by several turns of the screw, and, when deemed sufficiently constricted, the pedicle-pins were introduced just above the wire, and the uterus with its growth cut away half an inch above the pins, the stump appearing perfectly white and bloodless. Immediately after the amputation the wire was tightened by two turns of the screw, a point to which Bantock attaches much importance. The little blood that had escaped into the cavity was sponged out, and the abdominal incision closed down to the stump, some care being taken to stitch the parietal peritonæum to the stump immediately below the grasp of the wire, thus completely closing and protecting the cavity from such discharge as might take place from the pedicle. The excess of tissue was then trimmed off of the stump and its peritoneal covering drawn over its surface by stitches, the object being not only to limit the exposed portion, but also to compress it by the tightly drawn silk sutures. A few superficial stitches were now introduced to draw the skin more closely about the pedicle, and gauze carefully packed under the pins and about the stump. Iodoform was dusted over the wound and the usual dressings were applied. The operation was completed in about two hours and twenty minutes. The tumor weighed twenty-three pounds and a half. Patient showed but little shock, reacting promptly.

There is nothing in the progress of the case worthy of note except that the temperature remained under 100° F. The bowels moved on the fourth day without a laxative; the wound healed primarily throughout; the clamp was tightened from day to day by a few turns of the screw; there was never any suppuration at the pedicle. The stump mummified and dropped off on the twenty-second day, leaving a small cupped granulating depres-

* *Amer. Jour. of the Med. Sciences*, 1889.

sion, this healing in a short time. It is now seven months since the operation, and my patient has regained her former health and vigor. This case may be reported not only as one of recovery from operation, but as one of absolute restoration to health.

CASE OF EMPYEMA COMPLICATED WITH PULMONARY ŒDEMA.

*REMARKS.**

By F. HUBER, M. D.

Though the subject of empyema has but recently been discussed before this Section, I have taken the liberty to present the following case, in order to direct attention to a not infrequent complication and to lay stress upon a practical point in the management of cases complicated with pulmonary œdema of the other side.

The little patient, Jessie W., aged twenty months, was referred to me through the courtesy of Dr. D. Cook, December 5, 1889. Unfortunately, I was not able to see the child until midnight, though notified earlier in the evening that effusion was present, with œdema of the other lung. I found the patient, who had been ill sixteen days, in a very precarious condition, extremely restless, tossing about wildly, and crying incessantly. Marked orthopnœa present for several hours. Face and extremities cyanosed, pulse feeble, limbs cold, eyes sunken and heavy. Several drachms of brandy were given, and the child, seated in the mother's lap, was aspirated and about six ounces of purulent fluid were drawn off very slowly. Though the breathing became easier, the general condition was bad and the child was at once placed in bed with the head low, hot bottles being applied to the extremities and warm applications over the præcordial region. Very soon the little patient rallied and grew quiet, soon after fell asleep, and passed a fairly comfortable night. The next day, as the child had gained ground and looked considerably better, it was determined to operate, the œdema of the other lung having subsided. Accordingly, assisted by Dr. Cook, the child was placed on the healthy side and, without an anæsthetic, the chest was incised posteriorly below the angle of the scapula and a drainage-tube inserted. The cavity was now irrigated with hot water and an antiseptic dressing applied. Irrigation was only resorted to once or twice subsequently, to wash out the fibrinous masses. A sheet of rubber several inches square was placed over the opening to act as a valve. This innovation, however, did not impress Dr. Cook or myself very favorably, and was discarded after a few days. The subsequent course was favorable, and in less than four weeks not only had the lung expanded fully, but even the integumental wound had healed.

Hyperæmia or congestion of the lungs is a very grave complication, which may result in œdema and even cause free albuminoid and frothy expectoration, often terminating in asphyxia and death by suffocation—œdema, pneumonia serosa of Traube, acute albuminoid expectoration of the French authors.

When pulmonary œdema occurs as a complication of purulent pleurisy it always adds to the gravity of the case, and may be the immediate cause of death. The treatment should be prompt and bold. Stimulants of various kinds must be given and the chest aspirated without delay. The quantity to be drawn off must necessarily vary with the circumstances of the individual case. Even in a simple case of effusion there is ordinarily greater or less danger of producing fresh congestion and hyperæmia of the lungs in removing a large quantity. It must not be lost sight of that our purpose is to relieve the intrathoracic pressure, to free the overburdened heart, and to remove the symptoms of oppression. As has been well said, "slowness in the withdrawal of the fluid, as well as the small quantity drawn, lessens the probability of any unpleasant effect." Bowditch says: "I always draw with great deliberation; I pull so lightly upon the handle of the piston that it seems as if the fluid itself were pressing out from the chest and pushed the piston upward, my hand simply following the impulse."

If this be true of an uncomplicated case, the lesson applies with far greater force to a case in which the danger to be avoided already exists and presents itself to us face to face. Some years ago, after reading of a number of cases of empyema cured by aspiration, I was in the habit of withdrawing large quantities, and did not meet with any bad effects in simple cases of purulent effusion. In several instances in which œdema was present upon the other side, though the aspiration was slowly performed with a Dieulafoy instrument and the patient stimulated, the œdema progressed, and the cases resulted fatally within thirty-six hours. It is true the cases were unfavorable, the œdema of the lung being well marked; but, in the light of subsequent experience, I am forced to concede that, had the quantity drawn off been less, the circulatory changes would not have been so extreme within a comparatively short time and the failing heart might have regained its tone and the termination been more favorable. Since then three additional cases of empyema with pulmonary œdema have come under my observation. From four to six ounces only were drawn off, the patients stimulated, and the heart allowed to regain its force; the pulmonary œdema gradually subsided within six hours, and, as in the case reported above, subsequent incision with drainage was practiced, followed by recovery.

The complication, in my experience, occurs rather in the acute suppurative pleurisies, in which class, as a rule, the constitutional symptoms are severe, the effusion of fluid rapid, and the heart's action greatly enfeebled. It occurs early, too, in the history of the case—about the end of the first or second week. I have not met with it in the subacute or chronic variety, where the heart has a chance to accustom itself gradually to the extra work demanded. Its mode of onset, too, may be rather sudden. A child aged three years was left fairly comfortable on the morning of the seventh day of her illness; unforeseen circumstances prevented the evening visit. During the night I was called out and found the patient suffering from orthopnœa, cyanosed, with the usual symptoms of extreme air-hunger, and with a marked pulmonary œdema of the other lung. I was compelled to aspirate at 3 A. M., and drew off about four ounces, sufficient to relieve the urgent symptoms. The same afternoon, when Professor Jacobi saw the case, the danger was over. A few days later the child was operated on and recovered.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, JULY 19, 1890.

NEW YORK'S NEW WATER SUPPLY.

At the time of writing, the Croton water is flowing for the first time through the new aqueduct. It is given out that for the present the flow is to be allowed to continue only long enough to fill the Central Park reservoir, which is said not to have been full at any time during the last fifteen years; and that then the new aqueduct is to be emptied for a period of about six weeks to give an opportunity for finishing certain work on it considered essential to its enduring efficiency.

When the old aqueduct was built, in the first half of the century, it was commonly thought to be quite sufficient for a town of any size that the imagination of the wildest optimist could picture New York as likely to attain, but within forty years it showed its incapacity, and it may take its place by the side of the brownstone rear wall of the City Hall as a monument to the defective foresight of the citizens of New York, and by the side of the old lady's declaration, in colonial times, that she could foresee the time when New York would contain "fifty thousand inhabitants," wherein the old lady was a trifle behind her predecessor who had foretold the stretching of London to Greenwich. Water has been going to waste over the Croton dam for years; there has been "water all around, but none to drink." If it is beyond all practicable expedients to bring the whole of this water to town—and we do not understand that even the two aqueducts will do it—it seems to us, as we have stated before, that other sources of supply should be drawn upon, especially the one involved in Mr. Bartlett's scheme. It will not do to put off further undertakings of the kind until another water famine is upon us.

The temporary relief alluded to will come none too soon. The supply of water available in most New York houses has dwindled year by year until it reached its minimum this summer, when it would not run in the second stories of most houses during the greater part of the day, Sundays and holidays excepted, and often failed on the first floor, or came only in a fitful dribble; so that the illustration employed by one of the comic newspapers, in which it puts into the mouth of a matron the query, addressed to her husband, whether it would be better to wash the child's face or have boiled potatoes for dinner, is hardly strained. A water supply of good quality and adequate quantity is a sanitary necessity of the first magnitude, to say nothing of its importance to comfort. When the quantity falls off seriously the quality is almost sure to deteriorate. Organic impurities necessarily find their way into open reservoirs. When they are copiously diluted they are relatively or altogether harmless; when they gain access to small bodies of water they may be potent for evil. Fortunately, during our water famine there has been no widespread prevalence of disease attributable to drinking contaminated water, but in hundreds of ways our restriction has doubtless contributed indirectly to grave attacks of sickness, and all the more this summer, seeing that the supply of ice in the market is reduced almost beyond precedent, and its quality correspondingly questionable. Our impression is that it would be wise to allow the preliminary flow through the new aqueduct to continue through the few remaining weeks of warm weather, provided the nature of the work of perfecting the conduit admits of such a course.

ACROMEGALY.

Within the last few years this disease has been brought before the notice of the profession, and now cases are being found in all the large centers of clinical research. The credit of first having described this very strange affection is undoubtedly due to Marie, who made a study of certain cases at Charcot's clinic in Paris. His records have been published in the numbers of the *Revue de médecine* for the current year, and have attracted a great deal of attention.

Quite recently the description of a case was given at the meeting of the Association of American Physicians at Washington. In addition to the work done by Marie, M. Suza-Leite, another of Charcot's pupils, has collected all that is known of this strange disease, and, having added some original observations made at Charcot's clinic, has published a comprehensive treatise which embodies all our present knowledge of the subject.

The disease begins by a gradual thickening of the hands, which become uniformly enlarged, the other members not altering their form. But after the hands become enlarged a change comes over the face in that it becomes longer by a well-marked prognathism. The lower lip grows thick and pendulous, the nose becomes hypertrophied, the orbital arches become prominent, the lids thicken, and the skin generally undergoes pigmentation. Deformity extends to the trunk, lateral curvature of the spine takes place in the cervico-dorsal region, the ends of the ribs become prominent, and the patient comes to present a humpbacked appearance. In addition to these changes, the patient complains of headache, of pains in various parts of the body, of increased thirst and hunger, and of disturbances of vision, and in women amenorrhœa is wont to occur. These are the principal characteristics of the disease. But there are other less striking ones which are important from a diagnostic point of view.

For the first two years of its course the progress of the disease may be rapid, but at the end of that time a stationary period is reached, with occasional exacerbations of the symptoms already present, the patients eventually dying either by the cachexy induced or by reason of some cerebral lesion. They are lesions which belong especially to acromegaly, and it is doubtless a distinct disease. The lesion most constantly present is a considerable enlargement of the pituitary body,

which acts in all respects like a tumor at the base of the brain, and has all the accompaniments of such a structure—viz., compression of all cerebral structures, but especially those concerned with vision. The ganglia and the nervous cords of the sympathetic afford evidence of having undergone hypertrophy, the thymus is persistent, and lesions are found in the thyreoid body, the heart, and the vessels. After the changes in the pituitary body have occurred similar processes begin to take place in the bony parts, the sella turcica becomes enlarged, and other bony changes have been found.

The cause of this strange malady is obscure. It begins in adolescence or in mature age, and some of the patients give histories of antecedent mental shock, exposure to cold, rheumatism, or syphilis, but nothing is really known of its ætiology.

MINOR PARAGRAPHS.

AN INJUSTICE TO AN HONORABLE HOUSE.

Under the heading "Messrs Hazard, Hazard, & Co. sail under False Colors," the *Virginia Medical Monthly* says: "We have had occasion for some time to doubt the honesty of this firm, but were hoping that before this they would have relieved themselves of occasion for our suspicion. We have afforded them abundant opportunities to straighten themselves out in our estimation, but, as they seem entirely lost to those principles which regulate dealings with honest houses, we are painfully forced to recall any commendation we may have given this house in the past." The *Monthly* then appends a letter from Mr. W. F. Ford, which appeared in our issue for June 21st, as confirmatory of its unfavorable inference. The statements embodied in Mr. Ford's letter are true, but they are not the whole truth, and they do not warrant our Virginia contemporary's deduction. Mr. Ford says that he has "been manufacturing for the surgical profession continuously for over forty years," but he omits to state that for about half that period he was manufacturing under the firm now styled Hazard, Hazard, & Co. and that his connection with that firm ceased only very recently—so recently, in fact, that the statement in their advertisement to which he objects was simply the result of their failure to remove a standing notice instantly. We happen to know that they ordered its removal as soon as their attention was called to it. We regret exceedingly that our contemporary should have drawn from anything published in this Journal an inference in any way unfavorable to a house which for more than a century has deserved and received—and, we believe, still deserves and receives—the confidence of the medical profession.

THE ADMINISTRATION OF CHLOROFORM BY GASLIGHT.

Considerable attention has been given of late to the chemical composition of the compounds formed by chloroform vapor, air, and the products of the decomposition of coal gas. It appears from the investigations of several chemists (Stobwasser, von Iterson, Zweifel, and others) that chloroform vapor may be decomposed by gas flame and give rise to a compound of carbon and chlorine which is very irritating to the respiratory organs. This substance, along with others, forms a vapor in the neighborhood of the gas jet or of the petroleum flame. The operators sometimes experience pains in the head, nausea, and dizziness, while the subjects of operation suffer afterward from dyspnœa, cough, and lacrymation. Asphyxia in the course of the anæsthesia may develop at any moment and be followed by pulmonary complications. Kunekel's experiments (*Bulletin médical*) show that the chloroform is decomposed into hydrochloric acid, and he believes that it is that which does the mischief. He thinks that the effect might be counteracted by inhalation through linen soaked in an alkaline solution.

SUPPURATION AFTER CATARACT EXTRACTION.

In the *Klinisches Monatsblatt für Augenheilkunde*, according to the *Deutsche Medizinal-Zeitung*, Professor Adamük has brought together a large amount of statistical material from which he deduces that suppuration following a cataract extraction does not depend upon the traumatism inflicted during the operation, but upon infection. To prove this he quotes cases in which the greatest possible amount of traumatism was inflicted without any resulting suppuration, and contends that a clumsily performed operation is no more likely to be followed by this complication than one very skillfully performed.

THE ANIMAL PARASITES OF SHEEP.

The Bureau of Animal Industry of the Department of Agriculture has lately brought out a volume with this title, by Cooper Curtice, D. V. S., M. D., illustrated with thirty-six lithographs of the various parasites, mostly from original drawings. The diseases to which the parasites give rise are described, and their prevention and treatment are dealt with. The value of such a publication to those who are engaged in sheep-raising must prove very great.

THE MEDICAL REGISTER OF NEW YORK, NEW JERSEY, AND CONNECTICUT.

The twenty-eighth volume of this annual has just been received, being overdue a fortnight or more. The editor, in his preface, adverts to the fact that, in regard to the physicians of the city, the changes and removals have been unprecedentedly numerous, a fact which, while it has occasioned delay, makes the volume all the more important for reference purposes. Over 7,600 physicians find registration from the three States intended to be covered by this publication for 1890–'91.

THE UNIVERSITY OF THE CITY OF NEW YORK.

The fiftieth anniversary of the establishment of the Medical Department is close at hand, and that fact is made the occasion of a more than usually elaborate annual announcement, embellished with views of some of the lecture-rooms and students' laboratories. The announcement is made that during the half-century of its existence the institution has conferred the degree of M. D. on 5,832 matriculates.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 15, 1890:

DISEASES.	Week ending July 8.		Week ending July 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	8	0	26	6
Scarlet fever	43	2	44	5
Cerebro-spinal meningitis	2	2	1	1
Measles	271	23	240	19
Diphtheria	74	23	54	15
Varicella	4	0	3	0

The Astley Cooper Prize.—The *British Medical Journal* states that Mr. William Watson Cheyne, M. B., has received the award of

the triennial prize of three hundred pounds for the best essay on The Origin, Anatomy, Results, and Treatment of Tubercular Diseases of the Bones and Joints.

The American Public Health Association will hold its eighteenth annual meeting in Charleston, S. C., on the 16th, 17th, 18th, and 19th of December, under the presidency of Dr. Henry B. Baker, of Lansing, Mich.

The Ontario Medical Association.—At the June meeting, we learn from the *Montreal Medical Journal*, Dr. T. Addis Emmet, of New York, and Dr. E. M. Moore, of Rochester, were elected honorary members.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, for the week ending July 12, 1890:*

Robinson, Samuel Q., Captain and Assistant Surgeon, is relieved from temporary duty at the U. S. Military Academy, West Point, N. Y., to take effect upon the arrival there of Carter, W. Fitzhugh, Captain and Assistant Surgeon, and will report in person to the commanding officer, Fort Du Chesne, Utah Territory, for duty, relieving Price, Curtis E., Captain and Assistant Surgeon. Captain Price, on being relieved by Captain Robinson, will proceed to Fort Wadsworth, New York Harbor, and report in person to the commanding officer of that post for duty, relieving Benham, Robert B., Captain and Assistant Surgeon. Captain Benham, on being thus relieved from temporary duty at Fort Wadsworth, will report in person without delay to the commanding officer, Fort Hamilton, New York Harbor, for duty. Par. 12, S. O. 153, A. G. O., July 2, 1890, Washington, D. C.

Gardiner, John de B. W., Captain and Assistant Surgeon, having been found incapacitated for active service by an army retiring board, and having complied with Par. 12, S. O. 135, June 10, 1890, from this office, is, by direction of the Acting Secretary of War, granted leave of absence until further orders on account of disability. Par. 3, S. O. 153, A. G. O., July 2, 1890, Washington, D. C.

Taylor, Marcus E., Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence on surgeon's certificate granted in S. O. 45, June 13, 1890, Division of the Pacific, is extended five months on surgeon's certificate of disability, with permission to go beyond sea. Par. 6, S. O. 159, A. G. O., July 10, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending July 12, 1890:*

Rixey, P. H., Surgeon. Leave of absence granted for fifteen days.

Ogden, F. N., Assistant Surgeon. Promoted to be a Passed Assistant Surgeon.

White, S. Stuart, Assistant Surgeon. Promoted to be a Passed Assistant Surgeon.

Atlee, L. W., Assistant Surgeon. Granted three months' leave of absence.

Woolverton, T., Medical Inspector. To await orders to the U. S. Steamer Philadelphia.

Lovering, P. A., Passed Assistant Surgeon. To await orders to the U. S. Steamer Philadelphia.

McMurtrie, D., Medical Inspector. Granted leave of absence for — days.

Proceedings of Societies.

RICHMOND, VA., ACADEMY OF MEDICINE AND SURGERY.

Meeting of May 27, 1890.

The President, Dr. W. W. Parker, in the Chair.

A Nasal Concretion.—The President exhibited a specimen resembling wood coated with calcareous matter—the whole of about the size of a bicuspid tooth. A child of ten had expelled it from the nose in the act of sneezing; its presence there had been known for seven years.

Unusual Relation of Pulse and Temperature in Malarial Fever.—Dr. R. D. Garcin reported having observed in a case of malarial fever (in a girl of eighteen years), one evening, a temperature of 101° F., the pulse being normal. He had given no heart sedatives.

Salol in Dysentery.—Dr. Aaron Jeffery, having used salol in several cases of dysentery, reported very flattering results. Having failed with the ordinary treatment of the disease, he had ordered salol in powder, ten grains every three hours, with the result of disappearance of blood and mucus in about twenty-four hours.

Dr. Landon B. Edwards had been using salol in dysentery since attention had been called to its virtue by Dr. W. P. Nicolson, of Atlanta. He now preferred it to calomel and opium. He stated that the condition of pulse and temperature referred to by Dr. Garcin was common in malarial and typho-malarial fevers. He had observed in typho-malarial fever a pulse of 60 or 65 while the temperature ranged from 101° to 103°, probably being no higher from the effect of antifebriles. The condition of the pulse was so peculiar as to suggest idiosyncrasy, but an examination after recovery had discovered a normal rate.

Salines in Peritonitis and Typho-malarial Fever.—Dr. Edwards also called attention to the use of salines in peritonitis and typho-malarial fever. There had been hesitation and fear in regard to using the suggestion from lack of accuracy in differentiating typhoid and typho-malarial affections. He was confident that if this treatment was adopted a decided inroad would be made in the direction of shortening the duration of typho-malarial fever. This idea was sustained by eminent authorities. He had learned, since a correspondence with Dr. Joseph Price, that in peritonitis and typho-malarial fever the use of salines had become comparatively general in the North. He did not positively advocate this plan, but suggested it. Whereas a doctor would do well ordinarily to bring a case of typho-malarial fever to a close in fifteen or twenty days, he had completed two cases in about eight days with the use of salines and such antipyretics as acetanilide, antipyrine, and quinine. Fluid diet was as essential as medicines. In using the antipyretics he had guarded them with heart tonics, preferably strophanthus.

The President had observed, in reference to the abnormal relation of pulse and temperature, the pulse as low as 30 in some cases of typho-malarial fever.

Dr. O. A. Crenshaw stated, in reference to Dr. Edwards's remarks, that the treatment in 1845 had been with purgatives and venesection.

Dr. Edwards stated that salines were used not for their purgative but for their derivative effect.

Dr. Crenshaw believed that typho-malarial fever, so called, was nothing but typhoid fever modified by malarial poison as a result of the unfortunate hygienic conditions in our cities. In typhoid fever no purgatives should be used. In typho-malarial fever he followed the plan of purgatives in the beginning, and quinine.

Antipyrine in Malarial Fever.—Dr. Garcin asked the experience of any present in the use of antipyrine in malarial fever. He had found that it only controlled temperature while it was administered.

Antipyrine in Typhoid Fever.—Dr. Jeffery had found that in typhoid fever antipyrine reduced the temperature for the first few days, but afterward had no effect. He thought the drug too depressing to be safe, and that it did great harm in suddenly reducing high temperature, thus obscuring the true nature of the disease.

Dr. T. J. Moore, in reference to the saline treatment suggested by Dr. Edwards, asked if the natural history of these diseases had not been overlooked. The history of typhoid and typho-malarial fevers showed that they would run their course. He would therefore suggest palliative treatment. He did not like to tamper with new remedies until they had been proved of value. Where there was a tendency to ulceration of the bowel in typho-malarial fever the use of salines might set up a diarrhœa which it would be difficult to control. Quiet had been found very necessary in such conditions. In reference to peritonitis, salines might be resorted to where there was a pouring out of serum but not genuine pus. Wegner and one or two others had recommended, where there was an exudation of bloody serum but no true peritonitis, the use of salines to stimulate absorption.

Dr. Edwards feared that he might have been misunderstood. Where there was decided typhoid fever or ulceration present he would not advise salines nor had he ever seen them recommended. But in typho-malarial or bilious typhoid fever—the fever in which the leading element, bilious or malarial, as the case might be, was modified by a typhoid element (a furred tongue and constipated bowels distinguishing true typhoid)—salines might be used.

Sulphonal as a Hypnotic.—Dr. Jeffery reported the history of a case of a lady who, after taking thirty grains of sulphonal, slept from 6 P. M. on Saturday until 10 A. M. on Sunday; then, after an hour or two for breakfast, again slept until 4 P. M., and again from supper until the following morning. This was the only case in which he had observed such prolonged effect, although he had used the drug with success in various classes of wakefulness.

Dr. Crenshaw thought that sulphonal was an unreliable hypnotic.

The President had seen one case in which it seemed depressing.

Diabetes was the subject for the evening.

Dr. T. J. Moore opened the discussion. He said that there were two conditions under which sugar existed in the urine, known as diabetes mellitus and glycosuria. The first was characterized by the constant and persistent presence of sugar in greater or less quantity; the second was a transitory condition, where sugar made its appearance for the time being, but ultimately disappeared. In the former condition diet of a proper nature, and diet alone, would either greatly reduce the amount of sugar passed *per diem*, or would cause it to disappear during the time the diet was continued, to return, however, when it was left off. As to causes in diabetes mellitus, heredity played a conspicuous part, and it was liable to continue in the family for three or four generations. Mental emotions, nervous disturbances of all kinds—such as want, deprivation, exposure to cold, etc.—might give rise to it. Any irritation affecting the floor of the fourth ventricle—central lesions and pathological changes in the vicinity of this region frequently caused it—such as tumors, serous effusion, hæmorrhage, red and white softening, gummata, and interstitial changes of nervous matter. Gout, rheumatism, rheumatoid arthritis, pneumonia, typhoid and scarlet fevers, were all said to at times predispose to if not directly to induce it. Abstinence from animal and confinement to starchy foods was asserted by a certain class of authors to give genesis to it. The statistics would not sustain this declaration. Vegetarians and the residents of hot climates who subsisted chiefly upon vegetable diet were not specially prone to it. It was generally a disease of adult life, a limited percentage, however, occurring in children from five years upward. To enumerate the causes of glycosuria would necessitate repetition. Carbonic oxide, chloroform, ether, alcohol, strychnine, morphine, and the ingestion of large quantities of mineral acids, phosphoric especially, had been known to give rise to it. Uric acid in the gouty would likewise produce it. Anæmia following malarial poisoning, rheumatism, cholera, or prolonged lactation had been known to cause it. Abnormal conditions of the digestive tract and congestion of the pancreas sometimes caused glycosuria. Overwork, anxiety, and morbid mental disturbances occasionally produced it. Women undergoing the change of life, and broken-down aged people were liable to it. It was difficult to determine at first which of these conditions existed. In time the frequent examination of urine would alone solve the problem. Several of the conditions above enumerated as producing glycosuria would likewise produce diabetes mellitus. In the latter disease the range of the thermometer was peculiarly interesting. It was quite often as low as 93°, more often 97° and 97·5°. The specific gravity of the urine was high, frequently ranging from 1·028 to 1·045. The diurnal quantity of urine ranged from six to thirty pints, with a general average of six to twelve pints, and of sugar from three ounces to half a pound. Uric acid, hippuric and phosphoric, the lime and potash salts (oxalate of calcium in particular), and albumin—had all been found as accompaniments. The disease was an insidious one, often accidentally discovered in a general examination of urine.

The impression was prevalent that in true diabetes the career of one so affected was necessarily short. Severe cases, occurring in the weak, aged, or generally broken down, would average about two years. Under more favorable conditions patients would live from ten to twenty years. The appetite was voracious and difficult to satisfy. Thirst was continuous. As to morbid anatomy, the liver was most frequently congested without structural change; the kidney congested, punctated, and its epithelial cells fatty. The anatomical changes were confined to the convoluted portions of the tubules. The sacculated condition of the kidney was an occasional accompaniment. The heart was usually feeble, and there was an increase of the watery element of the blood, with decrease and disintegration of the red corpuscles.

Reflex disturbances were prominent. Neuralgia in brachial, femoral, dorsal, epigastric, and other regions was common. The skin was dry, harsh, and rough, with a yellowish tint. The mucous membranes were congested. The tongue was often red, streaked, and covered with thick, tenacious mucus. Sweating was common, with certain anatomical peculiarities. Often one side, a limb, the soles of the feet, or the palms of the hands, would alone be affected. Œdema of the extremities toward the termination was quite common.

Death was produced in various ways. Exhaustion and secondary lung complication were some of them, chronic pneumonia, without tubercular deposit, being a fertile source. Patients occasionally fell into coma and thus passed away. During the course of the disease various skin eruptions made their appearance, often in groups. Lichen, impetigo, eczema, furuncles, carbuncles, and gangrene were all found at times. Where the latter appeared, speedy death was almost inevitable. Gangrene of the lung occasionally carried off the patient. No satisfactory treatment had been discovered. The best results had been obtained from the treatment recommended by Dr. Banting for the reduction of obesity, with the addition of gluten biscuit, or those made from almond flour. It required from twenty-four to forty-eight hours first to find out by tests the quantity of sugar in the urine. Then, having put the patient upon the above diet, the urine should be examined in two weeks to observe progress. If the sugar was reduced one half at the end of three or four months, moderate success was being obtained. As to medicines, opium seemed beneficial. Its principle, codeia,

had been snggested. Mr. Ralph recommended the bimecolate of morphine. It was best to use the drug tentatively. Instead of several times a day, administer a fair dose at night, afterward increased if necessary. Tbe opium habit was apparently not so liable to be contracted hy these patients. Bromides and salicylates had also been used, and phosphorus when there was a nervous element; acids and pepsin when there was indigestion present. Steam baths and hot donches were beneficial for their effect npon the skin. Whatever the plan of treatment adopted, it would be likely to disappoint in most cases. Tbose improving rapidly and readily most prohably bad glycosnria, which would be relieved any way.

As to physiology, it was supposed that some congestion or irritation of the liver either interfered with the action of the cells, thus allowing the sugar to pass throngh nnchanged, or else caused an overstimulation of said cells, resulting in overaction of the sugar-producing fnnction.

Dr. Crenshaw recommended Waukesha Springs for diabetes. The Bishop of Canada had been apparently cured and many others greatly benefited hy this water. Siluria and Bethesda waters were also used. The speaker cited the case of a man in this city who, thongh rejected twenty-five years ago hy an insurance company on account of diabetes, was now living, thanks to Wahkesha water. He had dieted himself very little in the mean time. Carlshad water wonld probably benefit dyspeptic cases; opium those in which brain symptoms were manifested. He did not believe, however, that true diabetes mellitus could be cured.

Dr. Edwards mentioned that Balmanno Squire, of London, had recommended phosphorus as a specific cure for diahetes. Sqnire had prescribed phosphorus for a skin eruption npon a patient who also had glycosuria. The effect had been a cure of hoth. If there was any one remedy in the form of a drug, it would seem to be phosphorus. He thonght the henefit from the various springs was transient. Some years ago he had prescribed Buffalo Lithia Water for a clergyman afflicted with glycosuria. He had been apparently cured, but the trouble returned, and, in order to gain benefit, he had been compelled to alternate between Buffalo Lithia, Allegheny, Blue Ridge, and Raleigh.

Mr. Blair believed, as to the waters, that pure water was the secret of benefit; therefore he suggested distilled water. He thought that phosphorus would prove as ineffectnal as all other drngs. He believed a young subject affected with diahetes mellitus would certainly die; an old one would prohably prolong life by diet and otber means until killed hy some other disease. He related the case of a hospital patient wbo, not improving mnch, went to his work and, thongh he was not cured, he grew better from that time. The speaker wonld recommend employment. He would suggest in the way of food wheaten bread, cut very thin and toasted. Dextrin would not he so readily converted into sugar as starch. All the remedies that had been used appealed to the nervous system. Sugar in the urine was no proof of diseased kidney; hut that organ would be injured by the long-continued passing of snch quantities of water tbrough it. He had known of a woman (diabetic all her life) passing as much as a pound and a half of sugar *per diem*. He referred to a man in this city who for twelve years had been afflicted with diabetes. Six months ago he had been dieted, with the result of the disappearance of sugar. He was now dying from the effects of contracted kidney. Twelve years ago he had received a great mental shock, whicb was probably the cause of the diabetic trouble. Though he now passed large quantities of urine, the specific gravity was low. This was one of the symptoms of contracted kidney, due directly, however, to the hypertropbied heart.

AMERICAN NEUROLOGICAL SOCIETY.

Sixteenth Annual Meeting, held at Philadelphia, June 4, 5, and 6, 1890.

The President, Dr. E. C. Spitzka, of New York, in the Chair.

Unusual Forms of Chorea, possibly of Spinal Origin.—This was the title of a joint communication by Dr. S. Weir Mitchell and Dr. C. W. Burr. The first case described was one of inherited congenital chorea, possibly involving the spinal cord. Tbe patient, a young man eighteen years of age, had presented himself at Dr. Mitchell's clinic in 1889 complaining of constant involnntary movements of the legs, arms, and head. The history of the patient's family was of special interest in tbis case. His maternal grandmother had suffered from cborea for many years, not from birth, but she had while so affected given birth to the patient's mother, who was choreic from birth till deatb. Both the patient's parents had died of phthisis. There was no history of other cases of chorea or any nervous disease in the family. The patient's choreic movements began in early infancy, probably from birth. As a child he was puny and of tardy development. His present condition was that of a fairly bnilt yonng man of good strength, weighing one hundred and thirty pounds. Other tban the condition immediately associated with the chorea there was no physiological disturbance. The knee-jerk was increased on both sides, and the cremasteric, plantar, and abdominal reflexes were marked. Ankle clonus was occasionally present, and at times rigidity at the knee, the feet being then turned toward inward at the ankle. All the conditions were increased by emotion and the administration of moderate doses of strychnine. Sensation to touch, pain, and temperatnre were normal, and so was station. While awake, the patient's entire voluntary muscnlar system was more or less in action. Tbe sndden presence of a stranger emphasized the trouble. Dnring sleep there was perfect qniet. No spinal tenderness bad existed, urine was normal, and so, with some slight muscular insufficiency excepted, was vision.

Dr. Mitchell then read in detail the histories of two other cases in which the patients were hrothers, their father baving, at forty-five years of age, developed alleged choreic symptoms. The first of these two cases had resembled in general aspect canine chorea.

The authors of the paper thought tbe first of the series of three cases, in which the disease had run tbrougb tbree generations, extremely rare. That organic changes were present somewhere in the motor tract of the patient might, they thougbt, be admitted, because of the extreme chronicity of the affection, its resistance to all treatment, and the presence of very distinct ankle clonus and rigidity, these latter symptoms pointing to involvement of the cord. Wbetber the changes were confined to the cord it was more difficult to say. It was not wished to do more than indicate the spine as possibly implicated in all the cases.

Double Consciousness.—Dr. Mitchell then allnded to tbe notorious case of Ansell Brown, who had left his home, assumed another name, and, as asserted, had lived some time without knowledge of his previous existence. On regaining control of his proper identity he had returned. Hypnotism had been recently tried npon him. While under its influence the man's mind could be made to revert to incidents in his fictitious existence, wbile of his real identity be would then know nothing.

The Weather in Relation to Neuralgic Pain.—Dr. Mitchell related the history of a patient of his who had made elaborate stndies and observations of the effect of variations of the weather upon neuralgia, from whicb he was a great suf-

ferer. The scientific findings, briefly stated, were that the maximum of pain bore direct proportion to the prevalence of storms, and that the aurora was a certain precursor of neuralgic exacerbation.

Chronic Softening of the Spinal Cord; Senile Paraplegia.—Dr. C. L. Dana read a paper on this subject, narrating a case which he said established upon a firm foundation, for the first time, the fact that in the gray matter of the cord there might exist progressive softening from obliterating arteritis, just as was found in the brain. It also established the pathology of senile paraplegia, no convincing evidence as to the nature of which had, until recently, been adduced. The question of non-inflammatory softening of the cord had been but obscurely dealt with, or let entirely alone. Acute softening had been described, usually as synonymous with acute myelitis, but the term was wrongly used and should not be applied to inflammatory processes at all. It had of late been suggested that some of the cases of acute myelitis were in fact primarily necrotic processes, but evidence was lacking in substantiation. The case he would describe did not belong to the acute type, but was a chronic myelo-malacia.

The patient, an old man of seventy years of age, of whose early life little could be elicited except that he had been generally healthy, had about four years ago noticed some weakness of the legs. There was no pain. This condition had progressed until one year ago. There was complete disability to walk, incontinence of urine, and trouble with the rectal sphincters. When seen in 1889 the man had presented the characteristic appearance of senility. The symptoms of the disease were limited to the lower extremities, which were wasted and contractured. The knee-jerks were gone; there was also no clonus or trepidation. Sensation was everywhere normal—indeed, the condition was rather that of hyperæsthesia. No pains in the legs—girdle pains or bedsores. Up to the time of the patient's death, which had resulted immediately from exhaustion, the general symptoms had changed but little. The mind was clear, though senile. The only gross changes in the cord or membranes was noticed in the anterior horns in the sections taken low down. The more minute examination of microscopical sections had demonstrated the case as one of degenerative endarteritis with sclerosis, obliteration of the vessels causing the softening of the anterior horns and intermediate gray matter. This process was accompanied by secondary congestion, dilatation of small vessels and capillaries, but no hæmorrhages. The condition was one of softening of the cord, precisely analogous to the so-called softening of the brain. It was not inflammatory and could not be termed an anterior polio-myelitis. It was not a cell atrophy, and did not belong to the spinal forms of progressive muscular atrophy. While the change was, without doubt, largely a senile one, the cord did not correspond to the description of such conditions given by Leyden. The disease might, the speaker thought, be called a senile paraplegia from softening of the anterior horns due to obliterating arteritis.

Traumatic Neuro-psychoses.—Dr. G. L. Walton read a contribution to this subject in which he dealt exhaustively with the questions of pathology and prognosis in injuries inflicted upon the nervous system by railway collisions and similar accidents. Under the influence of Erichsen's views, functional and organic injuries were for a long time indiscriminately classed together under the ambiguous and misleading term spinal concussion, while a common prognosis was given to all, leaving the student in doubt as to whether the worst or best results might be anticipated. To H. W. Page was due the credit of having elaborately corrected this inaccuracy and of sifting out the comparatively rare cases of organic spinal disease, whose sad course and prognosis had been so long allowed to overshadow and include the more common cases in which no demonstrable lesion existed. To the latter class he had first applied the term traumatic neurasthenia. Dr. Putnam, in 1883, after reporting several cases of traumatic hemianæsthesia, had called attention to the importance of looking for evidences of typical hysteria, in the chronic as well as in the acute stages of so-called spinal concussion. Among those who had early inclined toward the modified views regarding the effects of trauma on the nervous system might be mentioned Dr. Dana, who, writing in 1883, had very appropriately added hypochondriasis to the two terms already applied. Spitzka had considered that spinal concussion could produce spinal irritation. These theories were in direct opposition to the idea advanced by Westphal—that a diffuse sclerosis was set up by the jar. This view had many followers, both in Germany and America. In a recent work by Clevenger, of Chicago, it was proposed to give to these cases the name "Erichsen's disease." This writer regarded the spinal sympathetic system as the starting point of the pathological process. Seguin, in Sajous's *Annual* for 1889, considered organic injury to the nervous system a rarity as resulting from the forms of trauma under consideration. Without exhausting the literature of the subject, it might fairly be concluded that there was at present a very general, though not unanimous, tendency to abandon the theory of spinal concussion, and to regard the majority of the genuine cases as identical with already recognized functional forms of disease rather than cases of organic spinal injury. Dr. Walton's experience had lead him from the first to regard disease of the spinal cord resulting from trauma as of comparative rarity, when no dislocation or fracture had occurred, while Seguin's conclusions regarding the preponderance of the subjective symptoms, and the degree in which we were generally dependent on the patients, were fully justified by the majority of the cases which had come under that writer's observation. In examining such cases for legal purposes, we should avoid the tendency of accepting the statements regarding previous health for fear of coincident trouble. Analysis of one hundred successive cases, where nervous symptoms were complained of and where the question of damages had arisen or was likely to arise, gave the following result: Two were cases of vertebral fracture, one of vertebral dislocation, one of injury to cervical nerve roots, two of neuritis, one of long-standing spinal sclerosis, one of old infantile paralysis, one of extensive atheroma, one of choroiditis, four of heart disease, one of cystitis of local origin, and two of severe constitutional disease; four of these seventeen had died. The remaining eighty-two cases, with the exception of the simulants, would come under the class designated as neuro-psychoses.

A Case of Complete Paraplegia cured by Operation.—Dr. F. X. Dercum presented a middle-aged man with the following history: This patient had in 1887 suffered severe pain in the arms and shoulders. The pain was referred to the principal nerve tracts in the arms. Some time after this he had lost power in his legs. Then about October of 1888, in addition to complete paraplegia, there was loss of sensibility, but with constriction pain about the upper portion of the chest. There was complete paralysis of both sphincters. Examination had revealed the fact that the man's back was very painful over the third, fourth, and fifth dorsal vertebræ. Thinking there might be some local cause for the paralysis, trephining was decided upon. The spines and arches of the first to the fifth dorsal vertebræ, inclusive, were accordingly removed. The dura was found somewhat abnormally resistant to the touch, and was opened. Adhesions existed between the dura and the pia. After the operation, which the man had borne well, he at once said that his pain was absent. A few days afterward he was able to feel his foot when touched. Then he was sensible that

his hands were cold, and was able in a few days more to move his toes. There had been a very gradual but steady progress toward complete recovery. He had also regained control of the sphincters. Whether the result was to be ascribed to relief from pressure or to reaction from the shock of the surgical operation, the speaker did not venture to suggest. The paraplegia was probably the result partly of pressure and partly of myelitis.

Pathological Findings in a Case of Athetosis.—Dr. G. M. Hammond presented a report on the pathological findings in the original case of athetosis, on which Dr. W. A. Hammond's description of athetosis had been based. After briefly referring to the case, Dr. Hammond stated that the portion involved in the lesion consisted of fibrous connective tissue. Topographically, the lesion was a lengthy one in the antero-posterior direction, parallel in its short axis with the internal capsule. Its posterior end invaded the stratum zonule of the thalamus in its posterior third, and the posterior third of the posterior half of the internal capsule. In its anterior extension it crossed the capsule, invading the posterior third of the outer articulus of the lenticular nucleus. The author called attention to the fact that the motor tract was not implicated in the lesion, and claimed that this case was further evidence of his theory that athetosis was caused by irritation of the thalamus, the striatum, or the cortex, and not by a lesion of the motor tract.

The President reported a case of hemi-athetosis in which the lesion was found to be in the same situation as the one in Dr. Hammond's case.

A Case of Locomotor Ataxia associated with Nuclear Cranial-nerve Palsies and with Muscular Atrophies.—Dr. Frederick Peterson reported the history of the above-named case. The patient had been under the writer's observation since March, 1890, but the features of the case had been previously described by Dr. Seguin in the *Journal of Nervous and Mental Disease* for May, 1888. It was the first of five cases of ophthalmoplegia reported by that author. As there had been so many new developments in the patient's condition during the past four years, it was thought best to briefly outline the history from the first observations made up to the time when he had come under the writer's notice. M. J. T., now thirty-seven years of age, had had a chancre and secondary symptoms fifteen years before. In 1882 he discovered one morning dimness of vision and external strabismus of the left eye, with diplopia. Subsequently shooting pains in the legs and arms had developed. In 1883 he had a momentary loss of consciousness. During this year he had been under specific treatment at Hot Springs for some time. In 1884 there was partial double ptosis. In 1886, when lost sight of by Dr. Seguin, the ptosis was a little greater and the bladder was paretic. There was mild paresis of the right hand. Dr. Seguin, writing in 1888, said of this case that some of the symptoms seemed to justify a suspicion of incipient "posterior spinal sclerosis." Since 1886 until the present time there had been gradual progress in the disease. The main features of the case might be summarized as follows: The patient had had a number of bilateral motor cranial palsies—namely, of the third, fourth, fifth, and sixth nerves. He had also exhibited slight traces of crossed paralysis for more than four years. Locomotor ataxia had developed, as was shown by the occurrence at one time of lightning pains and by the presence now of ataxia, widely distributed anæsthesias, failure of knee-jerks, ocular, vesical, and anal symptoms. Finally he presented marked trophic changes in numerous muscles. As to the morbid processes underlying these various manifestations, there was, in the first place, undoubtedly a sclerosis of the posterior columns of the spinal cord. The ophthalmoplegia was of course nuclear. Read in one way, the symptoms on the side of the cranial nerves, taken in conjunction with the muscular atrophies and paralyses elsewhere, certainly very closely resembled the syndrome so well described by Dr. Sachs in a paper last year under the title of Polioencephalitis Superior and Poliomyelitis. The most important matter to be settled in this case was whether the muscular atrophies were due to peripheral or central lesions. Speculation upon the question would seem to be of very little utility, and its solution must be left to the hoped-for autopsy. It had been assumed by a number of authors that total paralysis of all of the muscles supplied by the third nerve implied not a nuclear but a nerve-trunk palsy. In the writer's case all of the muscles of both third nerves were totally paralyzed, including both irides, and yet there was every reason to believe that the palsies were nuclear. It would at least be difficult to conceive of a lesion at the base of the brain so widely affecting the trunks of both third, fourth, and sixth nerves, and the motor portions of both trigemini, yet permitting the escape of the sensory portions of the latter.

Multiple Neuritis, or Beri-beri, among Seamen.—Dr. J. J. Putnam reported about twenty cases of a disease resembling beri-beri, but possibly another form of multiple neuritis, occurring among fishermen in northern latitudes, and referred to a similar series of cases reported by Dr. F. C. Shattuck in 1881. By correspondence with physicians in the seaport towns, Dr. Putnam had ascertained that, besides the larger epidemics, sporadic cases had occurred from time to time. One physician had reported frequent cases of swelling and numbness of the hands, attributed to handling fish. The influence of alcohol and the metallic poisons could be excluded; and, since the outbreak had occurred only now and then, the influences to which the seamen were habitually exposed could hardly be considered as the whole cause, though insufficient food had seemed to play a part in some instances. Most of the patients had recovered, but some had died.

On Cases of Postero-lateral Sclerosis, with Special Reference to the Pathology of the Disease.—Dr. Putnam referred to a series of eight cases of similar character, presenting the symptoms of "combined sclerosis" of the spinal cord, which he had seen during the past few years, and reported four of them, in which he had examined the cord microscopically. All the cases of the series, though differing in some respects, resembled each other as follows: All the patients were past middle life, and all were either anæmic or in a state of poor nutrition. The symptoms in all consisted in both motor and sensory disorders in all four limbs, sometimes associated with inco-ordination, sometimes not. The upper knee-jerk was exaggerated in all but two or three; in those it was absent. Tabetic pains were present in one case only. Anatomically, sclerosis was found in the posterior and lateral columns, varying in exact position. In almost every case the posterior change seemed the older and most intense. Besides the "typical" sclerosis, there was evidence of a more recent process, characterized by granule-cell formation and the breaking down of the nerve tubes so as to form circular or oval spaces. This new process was developed on the borders of the older change. The gray matter of the cord was more or less affected, and the nerve roots in about the same degree. The cases had all run a rapid course, terminating, after one to four years, in death, preceded by paraplegia due to non-inflammatory softening. Next to inherent structural weakness, as an ætiological factor, came impaired nutrition and toxic influences. The importance was pointed out of recognizing and attempting to meet the partial courses of the disease, of which several might be present at once. As special stigmata of degeneracy in these four cases, the writer referred to the mental condition and family history of several of the patients, to the remarkably abnormal shape of the cord in one,

the small size of the dorsal gray matter in another, and the presence of a second central canal in a third.

On Ingravescent Apoplexy.—Dr. C. L. Dana read a paper with this title. He said that there were three sets of intracranial blood-vessels—those in the dura, those in the pia mater, and those in the substance of the brain. We had, correspondingly, three types of intracranial hæmorrhage. The central hæmorrhages were far the most common, and presented a tolerably uniform clinical type. There was one form, however, which seemed to have escaped critical attention, though it could not be excessively rare. In 1876 Dr. Broadbent had reported six cases of what he termed "ingravescent apoplexy." In 1889 M. P. Puesch, of Montpellier, had also reported a case of the same character. The writer had met two cases presenting the general clinical characters of ingravescent apoplexy, but was able to make an autopsy upon only one, of which the history was as follows: A woman was brought to the hospital on May 1st without any history. She was in a stupid condition, but not unconscious, and she was at first thought to be intoxicated. Examination showed, however, some hemianalgesia of the left side and slight hemiplegia of the same side. The right pupil was slightly contracted, temperature normal, pulse tense. Next day the patient's mind was clearer; she answered questions, and recognized those about her. But the hemiplegia was very much worse, and the analgesia no better. Toward night she became more stupid, and finally comatose; œdema of the lungs developed. No contractures of the paralyzed side were noted. The temperature rose, and the patient died next day, May 3d. At the autopsy the brain was found congested. Pressure over the supramarginal gyrus showed that there was a softened place beneath it. The brain was placed in boroglycerin and alcohol, and opened later by vertical sections. These showed a clot in the lateral ventricle, and some blood in the third ventricle. Beneath the supramarginal gyrus was a large hæmorrhagic focus about an inch and a half in diameter. This extended forward and downward, cleaving the external capsule. The hæmorrhage had finally extended downward and inward and broken into the lateral ventricle. Puesch had attempted, on the slender basis of seven cases, to erect "ingravescent" or, as he called it, "progressive" apoplexy into a distinct type. This seemed to the author to be somewhat premature. The history of his case was not exactly like those of Broadbent's in respect to retention of consciousness, and the hemiplegia was relatively less marked. Yet, anatomically, it was one of the "cleaving" hæmorrhages due to rupture of a posterior branch of a lenticular artery, and running the same course as was described by Broadbent. The hemianæsthesia seemed to the author to be a very distinctive point. Practically, the question came up as to whether, in such cases, trephining would be justifiable. In general, the idea of trephining for non-traumatic hæmorrhage was not to be entertained at all. But in ingravescent apoplexy it deserved consideration, because here the hæmorrhage was accessible, and because, unless some relief was given, it would surely break into the lateral ventricle and kill the patient. In all the reported cases, also, the patients were not old, were not syphilitic, and presumably had not extensively diseased arteries. In reaching hæmorrhages in these cases, the best place to trephine would be a little below and in front of the parietal eminence. The surgeon should then explore downward and forward, care being taken not to injure the terminal branches of the Sylvian artery, which were in this neighborhood. In cases of "ingravescent" apoplexy, surgical interference, if undertaken, should be before the blood broke into the ventricles. This could be told by the sudden increase in the severity of the symptoms, and, if the blood was poured in rapidly, by contractures on the paralyzed side. The temperature changes were believed to be the same in the ingravescent as in ordinary apoplexy. The author trusted that the report of his case might excite the interest of others, and call attention to this apparently distinctive and fatal form of cerebral hæmorrhage.

Tumor of the Quadrigeminal Region, with Special Reference to Ocular Symptoms.—Dr. B. Sachs read a paper with this title. He had been fortunate enough to obtain two autopsies during the past year which bore upon this question, and had also seen several other cases which were subjected to careful clinical examination. His first case was one of unusually severe tuberculosis cerebri. The main points of the history he had been able to complete through the kindness of several colleagues. E. L., aged three years. The mother had noticed a change in the child's disposition for several months following an attack of measles. Examination had disclosed double and almost complete ptosis. There was no upward or downward movement of either eye. Both external recti muscles were thrown into clonic spastic condition when the attempt was made to use them. The interni were capable of very slight motion, but all the other ocular muscles were completely paralyzed. There was distinct accommodative power, with but slight reaction to light. Although in a semi-stupor, the child could be made to walk, exhibiting most distinct cerebellar staggering. Autopsy had revealed adhesions of the dura to the skull, with a slight increase of subdural fluid. A solitary tubercle was at once discovered near the right lateral sinus, pressing into the lateral edge of the cerebellum, and producing thrombosis of the lateral sinus. The cerebellum was the seat of the most profound changes. The base presented several unusual conditions. There was great thickening of the pia, with small tubercular deposits between the corpora mamillaria and the optic chiasm, and in the interpeduncular space. The thickening at this point was so great that both third nerves, instead of lying across the crura, after removal of the brain, pointed backward, and the right sixth was twisted out of its position. Section of the brain showed the tumor to occupy almost the center of the tegmental division of the crus, and that it had left a very small portion of the corpora quadrigemina and the brachia intact.

Mrs. L., aged forty years, had always enjoyed good health until four years ago, when she began to be troubled with headaches, vomiting, cerebral in character, and a peculiar sensation in the head on looking upward, with diplopia. These symptoms had increased until there was paresis of both internal recti. The externi acted fairly well, but nystagmus supervened if attempts were made to turn the eyes out. Upward movements of the eyes were barely possible: downward vision was limited. Knee-jerks and sensations normal. The diagnosis of opthalmoplegia nuclearis, probably polio-encephalitis chronica, was made at that time, but later abandoned, and the alternative of tremor accepted, for the patient had developed inco-ordination, with characteristic staggering, and was found to have double optic neuritis. No autopsy was obtained, but the idea of tremor in this case could hardly be rejected.

A young man, thirty-three years of age, had been under observation for several months. The patient had had chancre fourteen years ago, was thoroughly treated at that time, and had no symptoms since. The author found the patient with left ptosis, covering almost three quarters of the pupil, but could be raised slightly with great effort. Reflexes to light and accommodation were nearly normal; the left pupil was possibly a little sluggish to light. There were swelling and redness of the left optic disc. The left abducens was completely paralyzed; all other movements of the eyes were perfect. The patient was at once put on vigorous specific treatment, and kept on it for months, with no change in the condition, the general health remaining good. Was the lesion central or peripheral

The author could not conceive of a lesion at the base of such a character that only the sixth-nerve fibers and a few of the third-nerve fibers were affected. Such a selective disorder was within the range of possibility, but, until this was proved, the fear of a nuclear lesion could not be lost sight of in such a case as that just described.

Crus Lesion.—This was the title of a second paper by Dr. SACHS. Crus lesions, he said, were rarer than many other cerebral lesions, but their symptoms were well marked. The case under consideration had some special interest, however, in connection with post-hemiplegic disturbances of motion, and from this point of view the results of the post-mortem examination were worthy of consideration. Seven years ago the patient, a woman about fifty years of age, had had a dizzy attack one morning, and had found her vision rather blurred. There was a recurrence of the attack in fifteen minutes. There was no unconsciousness or difficulty with speech; but when the patient attempted to walk she found she could not with ease: by morning she had almost complete left hemiplegia; she could not open either eye. At that time speech was heavy and indistinct, but from this she had recovered in three weeks. Hearing, taste, and smell were altogether normal. The hemiplegia was never recovered from. The patient became somewhat unruly and demented, and was finally taken to the Montefiore Home, where she had remained for many years. A few further details of the patient's chronic condition were elicited in examination. There had been no history of syphilis, but there was very marked atheroma of the peripheral arteries. In addition to the left hemiplegia, the patient had suffered amputation of the right leg above the ankle, for old necrosis of the tibia, fully six years before. There was rigidity of the left leg, and increased knee-jerks of both sides. The wrist reflex was decidedly increased on the paralyzed side, but the left upper extremity was subject to the wildest ataxic movements. This would go on until the arm dropped from exhaustion, when it would remain quiet until aroused again by an effort to use the hand. She had become extremely emotional, took very little nourishment, and had finally died. The diagnosis of crus lesion of the right side, probably softening from thrombosis, was made, and confirmed by the autopsy.

Remarks on Therapeutics as applied to Nervous Disorders.—Dr. W. R. BIRDSALL read a paper with this title. While admitting that many of the diseases which the neurologist was called upon to investigate were practically incurable, the author maintained that those who saw no advance in the therapeutics of nervous diseases were probably looking in the wrong direction for progress, the advance being in great part the outcome of those very investigations considered by many as unpractical scientific refinements. The early diagnosis of disease he regarded as the most important factor for therapeutic success in diseases of the nervous system, as it frequently enabled the physician to check the course of the disease where marked disability had not yet resulted. Hygienic measures were considered of prime importance, and pharmacentical remedies as valuable accessories, in the treatment of these diseases. All relation between storage and expenditure must be readjusted to the disturbance in equilibrium, and the therapeutics consisted in bringing about such a readjustment by any means in our power. The modern craze for so-called physical culture, the author believed, was bringing forth dangers as great as those it was sought to remedy, through over-training, improper training, training for brain workers which fatigued rather than rested the brain, together with other faulty methods. Hydrotherapy he considered was much neglected, and electrotherapy overestimated. Next to hygiene, cutaneous irritation was decidedly the most important therapeutic measure possessed by the neurologist. Surgical interference and the drugs usually employed by the neurologist were briefly referred to.

Diffuse Cortical Sclerosis of the Brain in Children.—Dr. WILLIAM N. BULLARD read a paper with this title. He thought it was rather doubtful whether cases of cortical sclerosis could always be distinguished from forms of diffuse sclerosis in which the cortical layers were not specially affected. The history of a boy, aged twelve years, was given, in which, after an accident—a fall, striking the head on the curbstone—there had been gradual loss of mind with total paralysis of the left extremities, and death fifteen months after the accident. The autopsy had revealed œdema of the pia, chronic leptomeningitis, atrophy of the brain, with secondary chronic internal hydrocephalus, and chronic ependymitis of the fourth ventricle. Microscopical examination of the brain showed the first layer of the cortex, the fibrous network, to contain a few spider cells in the mesh due to atrophy of the nerve fibers, and an increase in the neuroglia. There was a slight degree of nerve-cell infiltration of the adventitial sheaths of the blood-vessels in the cortex. Beyond this there was nothing else abnormal. Provisional conclusions were that there existed in children a non-congenital form of diffuse cerebral sclerosis in which the cortical layers of the brain were more specially affected, and which was distinguished from the other forms by its appearance in healthy children, either without known cause or after traumata, by the steadily progressive character of its symptoms, and by the especial prominence of the gradually increasing dementia, which finally reached an extreme degree without a corresponding loss of motor power and while the sensation was comparatively unaffected.

Officers for the ensuing Year were elected as follows: President, Dr. Wharton Sinkler, of Philadelphia; vice-presidents, Dr. C. L. Dana, of New York, and Dr. S. G. Webber, of Boston; secretary and treasurer, Dr. Græme M. Hammond, of New York; councilors, Dr. J. A. Walton, of Boston, and Dr. L. C. Gray, of New York.

Special Articles.

LETTERS TO MY HOUSE PHYSICIANS.

By WILLIAM OSLER, M. D.,
BALTIMORE.

LETTER I.

FREIBURG, *May 17, 1890.*

DEAR L.: This is a charming town, beautifully situated at the southwestern end of the Black Forest, and with a medical faculty which attracts students from all parts of Germany and not a few from abroad. During the past few years the number of men in attendance has risen rapidly and the semester has reached six hundred. I met here my friend Ramsay Wright, of Toronto University, and together we saw much of interest.

Bäumler, who has charge of the medical clinic, is a man of about forty-five, and we are very much indebted to him for making our short stay here agreeable and profitable. He was in London at the German Hospital, and subsequently practiced there as a consultant for nine years, when he was called to the chair of medicine. The medical wards, containing about one hundred and twenty beds, are very conveniently arranged, and the plan of having a separate lecture-room for each department, which is almost universal at German universities, is very advantageous. There are three assistants, the first of whom, Dr. Reinhold, has been here three years, and, as is customary, is appointed for an indefinite term. The second and third assistants remain for one or two years. In addition, four men are named for periods of three months to act as clinical clerks in the wards.

To-day's routine was as follows: At 7 A. M. the professor gave a didactic lecture (of which five are delivered weekly) to about a dozen students, the small number being due to a holiday yesterday and in part, no doubt, to the fact that attendance upon these systematic lectures is not compulsory. The subject was Diseases of the Œsophagus, and spontaneous rupture, perforation, and hæmorrhage were discussed in a most exhaustive manner. Afterward, in his private room, Dr. Bäumler raised the question of the value of such teaching to the medical student and suggested that the same might be got in a shorter time from books. Possibly; and, though I am strongly opposed to our present system of over-lecturing, I could not but feel that the men who had listened and taken notes had got their information in a much more interesting and instructive manner than if they had read the subjects in any text-book. Indeed, I do not know of any one *Practice* which contained all the information given in the three quarters of an hour. The question must be discussed temperately, as it has two sides, one of which is ably presented in the May number of the *New Review* in a Lecture against Lecturing, by Professor Sedgwick.

One thing in the lecture-room pleased me greatly: around the walls were inscribed on each side—above the names of Hippocrates, Galen, Vesalius, and Harvey, and beneath these in groups—those of the great clinicians of all countries; and it warmed my heart to see, as the representatives of America, the names of Flint and of dear old Dr. Bowditch. At 8 o'clock the visit to the wards was made and new or specially interesting cases examined. In commenting upon a case of typhlitis, Bäumler spoke of the great frequency of recovery in this disease, which he thought, as is now almost universally accepted, was always at first an affection of the appendix. The tendency toward early operation was, in his opinion, at present too strong. I mentioned the case which we had in the wards a few months ago, and which was certainly a most encouraging one in support of early interference; but who can say whether the small localized abscess found by Dr. Halsted at the point of the appendix might not have healed, or at any rate subsided, as the inflammation had done in a previous attack? Still, no one will deny that the lad is not better without his rudimentary appendage.

At nine o'clock the students assembled in the large ward, in the center of which chairs were arranged on either side of a bed, a method which is followed in the case of fever patients, and other cases too ill to take to the auditorium. A *Practicant*, as a final student is called, was then asked to examine the patient before the class, and an hour was occupied in the thorough investigation of the case—one of typhoid fever. Comments were made on each interesting feature, and the symptoms summed up in a clear and orderly fashion, most instructive to the class, the members of which had an opportunity of afterward looking at the case. Typhoid patients are uniformly bathed whenever the temperature rises to 103° F., and no internal antipyretics are used. The good effects are not, it is thought, confined to the lowering of the fever. The mortality is here only about eight per cent. lower than in the ordinary symptomatic method; but you shall hear much more on this subject. A convenience which we do not always see in American hospitals is the stand in each ward for the examination of the urine, and a microscope with the necessary reagents. A clinic is held daily, and on Wednesday it lasts two hours; so we concluded that the Freiburg professor did a very full day's work before ten o'clock in the morning. In another ward we found waiting four candidates for the *Staats-Examen*—the test demanded by the State and which is a very formidable affair, lasting for several days in each subject. We then went to the post-mortem room to see a case of bullet-wound of the brain. Ziegler, the professor of pathology, came here last year from Tübingen, and lends additional strength to the faculty, as he is one of the most progressive of the younger generation of workers in his department. To English and American students he has become well known through McAlister's translation of his work on pathological anatomy, which has had an extraordinary success here, a sixth edition being in course of publication. He is a young-looking man, with a pleasing, frank manner, and he gave us a hearty welcome and asked us to come to the post-mortem room to see an examination of three students for the license (*Staats-Examen*), and a most practical test it was. The men drew lots for trunk, head, and position of scribe. The poor fellow who began the work had evidently not been a diligent attendant in the post-mortem room, for he bungled the inspection of the abdomen and thorax in a shocking manner. The examination of the heart—the *pons asinorum* of dissection—loosened his sweat centers, but Ziegler dealt with him most gently, considering the repeated aggravations. We could not wait to see the end, as it was a matter of several hours. In addition to this searching examination, there are others in pathological histology and general pathology. Von Kahlden, the Docent in pathology, showed us the laboratory, which is not large but very well equipped, particularly for histological work. We afterward spent a very pleasant evening with Ziegler and von Kahlden, both of whom are genial, sociable men. Ziegler must be most industrious, as, in addition to the teaching, which occupies, he said, at least three hours a day, the revision of his text-book has been continuously in hand, the editions having followed each other so rapidly; then he edits his *Beiträge*, which has become a most important pathological journal, and recently, in conjunction with von Kahlden, he has established the *Centralblatt für Pathologie*. By the way, I have sent out von Kahlden's new book on histological methods. Call the attention of S. to the section on Ehrlich's blood methods, which seems fuller than is usually given. To-day we saw Ziegler perform a most interesting autopsy before the class in a case of bullet-wound of the brain. Early in April the young lad had attempted suicide, and had discharged a revolver twice at his head. One bullet flattened against the frontal sinus, where it was found post mortem; the second passed through the left hemisphere to the occipital lobe, where it lay on the median surface close to the cuneus. There was a firm-walled tract in the course of the bullet. An operation for abscess had been performed yesterday, apparently only by enlargement of the original orifice and the insertion of a drainage-tube. There was extensive basic meningitis. The boy was hemiplegic and aphasic, but we did not learn whether an examination of his visual fields had been made, which would have been of great interest considering the position of the bullet in the occipital lobe.

One of the assistants showed us through the new surgical clinic, which is not yet completed. The operating theatre is very well arranged, with a composition stone floor and iron frames for the seats, so that the whole room can be flushed with the hose and thoroughly cleansed. Carbolic acid is the chief disinfectant, bichloride being rarely used, and the gauze for dressings is simply sterilized.

The Anatomical Institute is a fine new building, of about the size of one of the pay-wards, with a large lecture-room in the rear. Professor Wiedersheim is in charge, and, as is customary in German universities, is an anatomist in the wide and proper sense of the term, having to teach human and comparative anatomy and histology. One of his assistants takes the surgical anatomy, and this really meets the objection one often hears urged in America against a pure anatomist teaching medical students. In a well-equipped anatomical department how easy it would be to have one of the surgical assistants teach the senior students the surgical relations of the subject in special courses! The anatomical lecture-room is one of the best I have seen—high and spacious, with splendid light from the roof and sides. In the center of the arena is a trap-door with hydraulic arrangement, by which, on turning a key in the floor, a table ascends from the preparation-room below. Wiedersheim is a beautiful draughtsman, and the blackboards were covered with elaborate diagrams, in colored chalks, of the origin of the cranial nerves. In the schemata which he thus makes of the nervous system from day to day he always uses the same colored chalk to indicate the same structure at different levels.

A man who has brought much renown to the university is Weismann, the professor of zoology, whose writings on heredity and Darwinism have attracted so much attention. In a recent pamphlet, *Ueber die Hypothese einer Vererbung von Verletzungen*, he makes a strong criticism of the recorded instances of the inheritance of peculiarities of structure acquired by accident or disease. His collected essays have been issued in English by the Clarendon Press, at Oxford, and form, perhaps, the most notable contributions to the theory of evolution which have been made during the past decade.

We came to the conclusion that Freiburg had a most progressive university, and certainly, so far as medicine, pathology, and anatomy are concerned, the post-graduate student will find everything that he could desire.

Book Notices.

A Text-book of Obstetrics, including the Pathology and Therapeutics of the Puerperal State. Designed for Practitioners and Students of Medicine. By F. Winckel, Professor of Gynæcology and Director of the Royal Hospital for Women, etc., Munich. Translated from the First German Edition, with Permission of the Author, under the Supervision of J. Clifton Edgar, A. M., M. D., Adjunct Professor of Obstetrics in the Medical Department of the University of the City of New York. One Hundred and Ninety Illustrations. Philadelphia: P. Blakiston, Son. & Co., 1890. Pp. xxiii–17 to 927. [Price, $6.]

No one is better known for painstaking work than the author of this treatise, which is rather more voluminous than the average work upon obstetrics. Perhaps this may have resulted, in part at least, from the extensive opportunities which he has had for observation. Not only was he conversant with the experience of his father and grandfather in this field, but he also tells us that since 1864 the enormous number of 17,200 obstetric cases have been under his direction. We have a right to expect ripeness of opinion after such an experience. A noteworthy peculiarity in this, as well as in all other works on obstetrics, as a rule, is the painfully minute attention which is given to directions concerning the care of the pregnant and parturient woman. Perhaps it is a pardonable fault, if indeed it is a fault, to exceed in giving directions to an embryo accoucheur as to the simplest and most obvious requirements, but such a plan allows little scope for the quality which we Americans know as common sense, which ought to be an indispensable prerequisite to the practice of obstetrics.

With the arrangement of the various subjects in this book no fault can be found. It is progressive and judicious, and suited to the requirements of learners. The subject of extra-uterine pregnancy is unsatisfactorily treated of. Every one knows Winckel's preference for treating this condition with hypodermic injections of morphine, which seems, to us at least, a haphazard way of treating a most serious condition. There is no apparent change in his views of the pathology of this condition, notwithstanding the wonderful contributions of the past few years. Tait's name is not mentioned in this connection. This is bad for the book and does not hurt Mr. Tait. We do not know what the author's opinion of Mr. Tait personally is, and again Mr. Tait may not be right in his rather narrow view of the pathology of this subject, but no one who is writing a book or a chapter on extra-uterine pregnancy can afford to ignore Tait's contributions to this subject.

The author is generally inclined to be fair and generous in his treatment of Americans, but we do not agree to his statement that "clinical observation of normal and abnormal labors is at a very low ebb in North America, with the exception of New York, Boston, and Philadelphia." If this were strictly true it would be a sad commentary on the obstetric instruction which many hundreds of Americans have received in Germany and elsewhere in Europe. Again, he is in error when he says that the disproof of the statement that there are but few instances of contracted pelvis in the United States is seen in the great number of urinary fistulæ among parous women here. As a matter of fact, urinary fistula resulting from parturition is a rare accident with us nowadays. It would hardly be rash to say it was rarer than in Germany, and Emmet showed long ago, in collating his enormous experience upon this subject, that very many of his cases were imported from Europe. Such cases are usually sent to city hospitals for operation, and perhaps the great diminution in their number during recent years argues better obstetrics in Europe as well as in America. Winckel thinks the statement that there are few contracted pelves here is unjustifiable until thousands upon thousands of pelvic measurements have been made. In our opinion, a short cut to a conclusion which is equally valid is furnished by the fact that there are so few cases of lesion which results from contracted pelvis. This is not intended as any disparagement to the study of the anatomy of the bony pelvis, which has no doubt been too much neglected with us. The subject is here treated of by a master in a way which is both comprehensive and entirely intelligible.

The impression which one gets of Winckel the teacher and the obstetrician from the perusal of his book is one of great respect for his learning and for his conservatism. His idea seems to us the true one, that pregnancy and parturition are simply physiological processes, which, as a rule, require slight interference, and should not be interfered with or disturbed for slight causes. As to the work of the translator, it has been admirably done, and we congratulate him on so faithfully rendering into English the work of his teacher, from whom we doubt not he derived much healthful inspiration.

The Surgery of the Kidneys: being the Harveian Lectures, 1889. By J. Knowsley Thornton, M. C., Surgeon to the Samaritan Free Hospital, etc. Nineteen Illustrations. London: Charles Griffin & Company, 1890. Pp. vii–102.

Mr. Thornton has very happily arranged these lectures and has included most of what is at present known regarding the surgery of the kidneys. They form very entertaining as well as instructive reading, and are particularly valuable to the practitioner who can not devote much time to this subject.

Food in Health and Disease. By I. Burney Yeo, M. D., F. R. C. P., Professor of Clinical Therapeutics in King's College, London, etc. Philadelphia: Lea Brothers & Co., 1890. Pp. x–583. [Price, $2.]

The author has aimed to make this work one of practical utility and to render it as far as possible representative of the subject that it treats of. It is concise, suggestive, and available for emergencies as well as for conditions requiring careful study. Diet in gastric disorders, diabetes, gout, anæmia, consumption, etc., receives careful attention according to the dictates of modern research.

May's Diseases of Women, being a Concise and Systematic Exposition of the Theory and Practice of Gynæcology. For the Use of Students and Practitioners. Second Edition, revised by Leonard S. Ray, M. D., Attending Gynæcologist to Harlem Hospital, Outdoor Department, New York, etc. With Thirty-one Illustrations on Wood. Philadelphia: Lea Brothers & Co., 1890. Pp. xii–25 to 373. [Price, $1.75.]

That such works as this are necessary is shown by the call for a second edition. The author disavows any originality in the work, and states plainly that it is only a compilation from standard authors. As a quiz book or a book of reference for one who is too much occupied to consult the sources from which this is drawn, it will play a useful part.

BOOKS AND PAMPHLETS RECEIVED.

Mineral Springs and Health Resorts of California, with a Complete Chemical Analysis of every Important Mineral Water in the World. Illustrated. A Prize Essay. Annual Prize of the Medical Society of the State of California, awarded April 20, 1889. By Winslow Anderson, M. D., Assistant, Chair Medical Chemistry and Materia Medica,

and Teacher of Chemistry in the Laboratories of the University of California, in the Medical and Dental Departments, etc. San Francisco: The Bancroft Company, 1890. Pp. xxx–3 to 384. [Price, $1.50.]

Rheumatism and Gout. By F. Leroy Satterlee, M. D., Ph. D., Professor of Chemistry, Materia Medica, and Therapeutics in the New York College of Dentistry, etc. Detroit: George S. Davis, 1890. Pp. 83. [The Physician's Leisure Library.]

Philosophy in Homœopathy. Addressed to the Medical Profession and to the General Reader. By Charles S. Mack, M. D., Professor of Materia Medica and Therapeutics in the Homœopathic Medical College of the University of Michigan at Ann Arbor. Chicago: Gross & Delbridge, 1890. Pp. 7 to 174.

Leçons sur les maladies du larynx. Faites à la Faculté de médecine de Bordeaux (cours libre). Par le Dr. E. J. Moure, Professeur libre de laryngologie, otologie et rhinologie, etc. Recueillies et rédigées par le Dr. M. Natier, Ancien chef de clinique du Docteur E. J. Moure, et revues par l'auteur. Avec des figures en noir dans le texte. Paris: Octave Doin, 1890. Pp. iv–599.

Die Protozoen als Krankheitserreger. Von Dr. L. Pfeiffer, Geh. Med. Rath und Vorstand des Grossh. Sächs. Impfinstituts in Weimar. Mit 34 Abbildunden im Text und 1 Tafel. Jena: Gustav Fischer, 1890. Pp. iv–100.

Die Untersuchung der hinteren Larynxwand. Von Dr. Gustav Killian, Privatdocent für Laryngologie und Rhinologie in Freiburg i. Breisgau. Mit 40 Abbildungen in Texte. Jena: Gustav Fischer, 1890. Pp. 77.

Transactions of the Southern Surgical and Gynæcological Association. Volume II. Second Session, held at Nashville, Tenn., November 12, 13, and 14, 1889.

Transactions of the Medical Society of the State of New York, for the Year 1890.

A Digest of Current Orders and Decisions, with Extracts from Army Regulations relating to the Medical Corps of the U. S. Army. Compiled under Direction of the Surgeon-General by Charles R. Greenleaf, Major and Surgeon, U. S. A.

International Atlas of Rare Skin Diseases. Editors: Malcolm Morris, London; P. G. Unna, Hamburg; L. A. Duhring, Philadelphia; H. Leloir, Lille. I and II. Philadelphia: J. B. Lippincott Company, 1889.

The Operative Treatment of Hip Disease. By De Forrest Willard, M. D. [Reprinted from the *Medical News.*]

The Treatment of Local and General Peritonitis. By W. E. B. Davis, M. D., Birmingham, Ala.

Report of the Ladies' Health Protective Association of New York, 1888 and 1889.

Primary Cancer of the Gall-bladder and Bile-ducts. By J. H. Musser, M. D. [Reprinted from the *Transactions of the Association of American Physicians.*]

Case of Tubercular Pericarditis; Unusual Amount of Effusion; Accidental Paracentesis Pericardii. Notes of the Treatment of Peritonitis. By J. H. Musser, M. D.

The Prophylaxis of Tuberculosis. By Karl von Ruck, B. S., M. D. [Reprinted from the *Therapeutic Gazette.*]

A Study of Metastatic Carcinoma of the Stomach. Report of a Case of Primary Carcinoma of the Testicle; Secondary Involvement of the Vena Cava Inferior; Metastases in the Lungs, Stomach, and Falx Cerebri. By John S. Ely, M. D. [Reprinted from the *American Journal of the Medical Sciences.*]

Chips from a Surgeon's Workshop. Five Consecutive Cases of Gunshot Wounds of the Abdominal Viscera treated by Abdominal Section. Two Deaths, Three Recoveries. By A. C. Bernays, M. D., St. Louis. [Reprinted from the *St. Louis Medical and Surgical Journal.*]

Aus der gynäkologischen Abtheilung des St. Francis Hospitals in New York. Die Laparotomien des Jahres 1889. Von Dr. George M. Edebohls, New York. [Aus der New Yorker *Medicinischen Monatsschrift.*]

Sifilide congenita tardiva. Nota clinica del dott. Umberto Dieci. [Estratto dalla *Rassegna di scienze mediche.*]

Nefrectomia transperitoneal. Por el Dr. Raimundo Menocal. [Publicado en la *Revista de Ciencias Médicas.*]

Ueber das mechanische Latenzstadium des Gesammtmuskels. Von Dr. Med. W. Cowl. [Separat-Abdruck aus den *Verhandlungen der physiologischen Gesellschaft zu Berlin.*]

Miscellany.

Coca and its Therapeutic Applications.—M. Angelo Mariani's monograph on this subject has already been mentioned in this journal. Dr. Henry Schweig speaks of the author's researches as having extended over a period of more than twenty-five years, not only in the preparation of laboratory products, but in matters pertaining to the cultivation of the plant with special reference to the higher development of its active principles.

ANSWERS TO CORRESPONDENTS.

No. 326.—If your diploma was not issued by a college situated in the State of New York, it will have to be certified to before you can register here.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

THE DOSAGE AND ADMINISTRATION OF CREASOTE IN PHTHISIS.*

BY WILLIAM H. FLINT, M. D.,
ATTENDING PHYSICIAN AT THE PRESBYTERIAN HOSPITAL.

MEDICAL opinion is at present almost unanimously favorable to the use of pure beech-wood creasote in phthisis, and convincing proofs of the efficacy of this remedy have been furnished by many authors on both sides of the Atlantic. Among the most valuable contributions of our own countrymen to the earlier demonstrative literature of this subject, the papers of Dr. Beverley Robinson deserve particular mention and are widely quoted. Our journals are, moreover, constantly heralding new and striking successes attained by the use of creasote, so that it no longer seems necessary to cite cases in proof of the value of this medicament.

In view, however, of the divergent opinions expressed by competent observers regarding the dosage and the administration of creasote, the writer hopes that the society will consider as opportune a discussion regarding the quantity of the drug to be employed and the best methods of its exhibition.

With a view to the inauguration of such a discussion, the writer begs to present the recommendations of some of the authors whose articles have come to his notice, as well as the results of his own observation and study.

Bouchard and Gimbert (*Gazette hebdomadaire*, 1877, pp. 486, 504, 522, and 620), to whom belongs the credit of rescuing the creasote treatment of phthisis from the oblivion to which it had been consigned after its discovery by Reichenbach, in the early part of the nineteenth century, suggested six or seven drops as the average daily dose of creasote, but recommended that this quantity be increased in the event of its being easily tolerated. Their favorite formula was the following:

℞ Creasote..... ♏xxxj;
Tincture of gentian..... ♏lxxij;
Alcohol..... ℥ x;
Tokay or Malaga wine..... ℥ v.

Dose, from ℥ j to ℥ ss.

Dr. Beverley Robinson (*Medical Record*, Sept. 2, 1878, p. 223), who may be called the apostle of the creasote treatment in this country, at first used the creasote mixture of the U. S. Pharmacopœia in dessertspoonful doses. This mixture is composed of creasote and glacial acetic acid, each, ♏xvj; spirit of juniper, fl ℥ ss.; syrup, fl ℥ j; distilled water, fl ℥ xv, and each ounce contains one minim of creasote.

A few years later Dr. Robinson (*N. Y. Medical Journal*, Nov. 14, 1886, p. 535) adopted the method of antiseptic inhalations in his treatment of phthisis, using, by preference, a mixture composed of equal parts of creasote and of alcohol, or of creasote, alcohol, and chloroform.

In the *American Journal of the Medical Sciences*, January, 1889, Dr. Robinson published a comprehensive and masterly article on the whole subject of the use of creasote in phthisis, to the results of which later researches have certainly added but little. In the course of this article Dr. Robinson again described his method of using creasote inhalations, recommending the inhaler now generally known by his name and several solutions well adapted for use in this inhaler. The solutions employed by Dr. Robinson are three in number, and their composition is as follows:

First, one recommended by Dr. Brunton and modified by Dr. Robinson:

℞ Iodoform..... gr. xxiv;
Creasote..... ♏iv;
Oil of eucalyptus..... ♏viij;
Chloroform..... ♏xlviij;
Alcohol, Ether, ... āā q. s. ad fl ℥ ss. M.

Second, the formula of Dr. Coghill (*Brit. Med. Jour.*, 1881, vol. i, p. 84):

℞ Tr. iodi ætherealis, Acid. carbolici, ... āā ℥ ij;
Creasot..... ℥ j;
Spts. vin. rect..... ad ℥ j. M.

Third, Dr. Robinson's own prescription:

℞ Creasote..... ℥ j;
Alcohol..... ad ℥ ss. M.

The inhaler was worn by Dr. Robinson's patients at first for fifteen or twenty minutes every three hours, and from ten to twenty drops of the mixture were placed upon the sponge at least three times in twenty-four hours.

For internal administration Dr. Robinson employed the following formula, which he adapted from Jaccoud and which has, I think, come into pretty general use:

℞ Creasoti..... ♏vj;
Glycerini..... ℥ j;
Spts. frumenti..... ℥ ij.

M. Sig.: As directed.

The dose of this preparation generally used was one teaspoonful, and this was given every three hours, diluted with two parts of water to prevent irritation of the throat and stomach. Dr. Robinson contended that creasote should be taken, at first at least, in small or moderate doses, continued a long time, and increased very gradually. His average daily dose was from three to six minims, and this quantity he administered, uninterruptedly, for many months.

Dr. Austin Flint (*N. Y. Medical Journal*, Dec. 8, 1888, p. 617) used doses of three or four drops thrice daily, and inhalations of the creasote, chloroform, and alcohol solution already described, at first for a few minutes, three times a day, and then for increasing periods even up to four or eight hours a day.

Professor Sommerbrodt, of Breslau (*Therapeut. Monatshefte*, July, 1889; *N. Y. Medical Journal*, Oct. 5, 1889, p. 373), strongly advocates the use of creasote in heroic doses, acting upon the assumption that enough creasote may be given to so charge the blood with the remedy as to antagonize the development of tubercle bacilli.

Professor Sommerbrodt bases his method upon the re-

* Read before the New York Clinical Society, May 23, 1890.

searches of Dr. P. Guttman, whose experiments showed that tubercle bacilli could hardly be cultivated in sterilized serum containing $\frac{1}{4000}$ volume of creasote, and that the culture could not be carried on if the solution were a little stronger than 1 in 4,000.

Professor Sommerbrodt has tested his method in hundreds of cases, using capsules each containing one minim of creasote. He usually begins the treatment with three capsules the first day, and adds one capsule on each succeeding day until the eighteenth day, after which the maximum quantity, from twenty to twenty-five minims *per diem*, is administered for many consecutive months.

Professor Sommerbrodt reports most gratifying results from this method and states that, in his experience, his success in any given case was in direct ratio with the amount of creasote taken. One of his patients took nearly nine ounces of creasote and thirty-five ounces of Peruvian balsam between September 1, 1888, and June, 1889, with very good results.

Dr. P. Bogdanovitch (*Meditzinskoe Obozrenoë; British Med. Journal*, March 10, 1888, p. 548) published the results of his experience in his own case of pulmonary and laryngeal phthisis. For two years he took doses of half a grain, four or five times daily, without effect. He then augmented the dose, commencing with four grains daily and increasing the quantity within two months to *forty-four grains* in twenty-four hours. The results were speedy amelioration, as regarded the cough and dyspnœa, diminution of sputum, and disappearance of fever and laryngeal spasm. The bacilli remained just as numerous as at the beginning of the treatment. Dr. Bogdanovitch infers from his experience that five grains should be taken four times a day in capsules, after food. This heroic Russian method may do well in the iron-bound realms of the Czar, but would hardly be adapted to the average invalid's stomach in these latitudes.

Even Dr. Bogdanovitch experienced epigastric discomfort after taking small doses on an empty stomach. This symptom did not present itself when even twelve grains were taken after meals. If, however, twelve grains were taken at a single dose, or twenty grains within an hour, Dr. Bogdanovitch suffered from giddiness, cardiac palpitation, weak pulse, asthenia, pallor, and anxiety. All of these toxic symptoms disappeared within half an hour or an hour, and did not return. The condition of the urine was not reported.

Dr. Lanisniée (*Union médicale*, quoted by *Brit. Med. Jour.*, 1888, i, p. 1360) claimed that nausea and vomiting from creasote might be avoided by the use of the following formula:

℞ Creasote..... 5 centigrammes;
Balsam of Peru..... 7½ decigrammes;
Norway pitch..... 7½ "

Sig. Make one capsule.

Four of these capsules are taken with the meals, morning and evening, and the dose gradually increased to twelve daily.

Dr. Rosenbusch (*Przeglad Lekarski*, Feb. 4 and 11, 1888, and *Wien. med. Presse*, June 10, 1889; see *Therapeutic Gazette*, May 15, 1888, p. 359, and London *Lancet*, 1888, i, p. 643) reported good results from pulmonary injections of creasote in phthisis. He injected eight minims of a three-per-cent. solution of creasote in almond-oil into each of two spots in the diseased lung at intervals of two or three days. The points selected for the injections were either the second intercostal space or the supraspinous fossæ. Dr. Rosenbusch alleged all the good results for this method obtained by other modes of administering creasote. The only unpleasant symptom following the injections was pleuritic pain, when the injections were too near the pleural surface. No hæmorrhages occurred after the injections, but the sputum of one patient who had already suffered from hæmoptysis was slightly colored for a short time.

Other observers have not been able to attain the good results alleged by Dr. Rosenbusch for intrapulmonary injections of creasote.

Dr. T. Stachiewicz (*Year-Book of Treatment*, 1890, p. 34) carefully employed Rosenbusch's method and found that cough and expectoration notably increased after each injection of creasote. Dr. Stachiewicz concludes that, if cavities have formed, creasote injections may cause rapid destruction of pulmonary tissue by engendering inflammation. Dr. Stachiewicz also believes that hæmoptysis is likely to follow intrapulmonary injections.

Dr. Mackey (*Brit. Med. Jour.*, 1888, No. ii, p. 765) used intrapulmonary injections of a three-per-cent. solution of creasote in olive-oil. The seventh injection, however, caused hæmoptysis and increased the inflammatory symptoms so that the treatment was abandoned.

Dr. J. Rosenthal (*Berlin. klin. Wochenschrift*, 1888, 32, pp. 640, 666) advocated the use of carbonic-acid water as a menstruum for creasote. This suggestion was based upon the result of many experiments conducted by Dr. Rosenthal regarding the effect of solutions of creasote in carbonated water upon cultures of thirty-two varieties of micro-organisms. Rosenthal found that the growth of the micro-organisms was almost or quite arrested by carbonic-acid water containing 1 part in 2,000 of creasote. Other experiments made by Rosenthal showed that creasote, even in weak solutions, will not only hinder the growth of the micro-organisms, but will actually kill the latter. Rosenthal's experiments also demonstrated that a sufficient quantity of creasoted water can be given hypodermically to a rabbit to make a dilution of one to four thousand in its blood without causing appreciable morbid symptoms. Creasote solutions of this strength were shown by Koch to greatly retard the growth of tubercle bacilli in various culture media. Thus, by inference, Dr. Rosenthal assumes, as did Sommerbrodt, that a sufficiently concentrated solution of creasote may be made in the blood to directly antagonize the growth of the bacilli tuberculosis.

Rosenthal recommended that the carbonated creasote water be prepared of such strength that each litre should contain from 0·6 to 1·2 of creasote and 30 grammes of cognac. The doses of this solution are so arranged that 0·3 of creasote is taken on the first day, and the remedy gradually increased until the daily dose is 0·8.

Von Driver (*Berlin. klin. Wochenschrift*, 1888, No. 35

see *New York Medical Journal*, June 1, 1889, p. 615) used creasote mixed with alcohol and sherry wine, according to the formula of Fräntzel, which is as follows:

℞ Creasoti..... ♏xv;
Tr. gent..... ♏vj;
Spts. vin. rect..... fl ʒ vj;
Vini xerici.....q. s. ad fl ℥ iv.

Sig. ʒ ss. t. i. d., with water.

Dr. von Driver believed in the heroic method, and increased his doses as rapidly as possible until the maximum was reached. This maximum was 0·75 gramme (*i. e.*, 11¼ grs.).

Groh (*Wien. med. Blätter*, No. 27, 1889) administered creasote in wafers intimately mixed with powdered cacao.

Dr. James E. Newcomb (*Medical Record*, August 10, 1889, p. 145) reported favorably concerning the effect of creasote in his service at the Roosevelt Out-patient Department. He administered the creasote by mouth only, and used the following formula:

℞ Creasoti, Tr. capsici, ...āā ʒ ij–ʒ iij;
Mucilag. acac..... ʒ ss.;
Aquæ.....ad ℥ iv.

M. Sig.: ʒ j, well diluted with water, after meals.

Dr. Ruetimeyer (*Brit. Med. Jour.*, 1889, i, p. 102) uses creasote in emulsion with olive-oil, almond-oil, or cod-liver oil, in which form it is fairly palatable and causes hardly any indigestion.

Dr. Dor (*Revue de méd.*, February, 1890; *Am. Jour. of the Med. Sci.*, May, 1890, p. 521) advocates the use of intra-tracheal injections of sterilized olive-oil containing creasote in the proportion of one part of creasote to twenty of oil, continued for many months. Dr. Dor injects 31 minims of this mixture, containing 3·1 grains of creasote, twice daily, and reports that he never observed untoward results—such as hæmoptysis, fever, or pleuritic pain—to follow the injections. After the injections the patients are made to assume positions adapted to facilitate the gravitation of the creasote to the diseased part of the lung. The fact of its penetration is evidenced, according to Dor, by the production of subcrepitant râles. Dr. Dor maintains that the digestive disturbances often resulting from the internal administration of creasote were entirely absent in his cases.

This observer's experiments with animals showed that the oil reached the alveoli and remained there for fifteen days in some cases before undergoing complete absorption.

The writer's experience with creasote in phthisis embraces seventy-three cases, among which there have been examples of all stages of the disease.

The cases were divided into three classes, according to the methods of treatment adopted—

1. Those in which creasote inhalations were alone employed.

2. Those in which creasote was administered both by inhalation and by the stomach or the rectum.

3. Those in which the drug was given only by the stomach or the rectum.

This subdivision of the material was made with a view to ascertaining which mode of administration yielded the best results, or whether a combination of both modes was most advantageous.

There are so many variables in a clinical problem of this sort that statistics upon a large scale are, of course, necessary to definitely settle the question. So far, however, as the limited experience of the writer goes, it tends to show that neither of the above-mentioned methods *invariably* furnishes the best results. The inhalation method was, naturally, most successful for patients whose gastro-intestinal tracts were diseased, while the other methods were more satisfactory, producing more immediate and even phenomenal results, in cases whose digestive organs were in a fairly healthy condition.

The solution used for inhalation was always that containing equal parts of creasote, alcohol, and chloroform. This combination was very acceptable to the patients, save in a few cases in which it caused nausea and gastric distress whenever employed. The inhalers used were Dr. Robinson's and that of the Brompton Hospital. In mild cases the inhalations were administered for fifteen minutes, every two or three hours; and in severe ones, every hour during the day-time and every three hours at night. From ten to fifteen drops of the solution were placed upon the sponge about every five hours during the day, and twice during the night. The writer employed several preparations for the administration of creasote by the mouth and the rectum. At first he relied upon the solution recommended by Jaccoud, and composed of creasote, ♏vj; glycerin, ʒ j; and whisky, ℥ ij. This was well borne by strong stomachs, but presented the disadvantage that the dose could not be greatly increased without the exhibition of an undesirably large amount of glycerin and whisky. The former of these medicaments in large quantities perhaps engendered gastric distress quite as much as the creasote, and produced too free peristole of the stomach. The use of whisky in the early stages seemed contra-indicated when there was little need of stimulants, and also exposed patients to the risk of contracting an undue fondness for alcohol, which might outlast their disease. For these reasons the writer early adopted the use of an emulsion composed of cod-liver oil, 40 parts, and mucilage of acacia, 60 parts—each drachm containing two minims of creasote. This was generally better tolerated than the glycerin and whisky, particularly when given after food. In suitable cases the emulsion was given every two hours, and the dose increased up to the point of toleration, which, in the majority of the cases, was about ten or twelve minims *per diem*.

In many instances, when the patients could be persuaded to temporarily adopt an exclusively milk diet, the creasote emulsion was administered in the milk, being thoroughly mixed with the latter by means of energetic shaking. The succussion may be well performed in an ordinary bottle or by means of a lemonade-shaker, such as is habitually employed by bar-tenders in preparing various beverages. The writer succeeded in administering more creasote in this manner, without exciting gastric symptoms, than by any other method, and can heartily recommend it for cases requiring large doses of creasote, frequently repeated. In a few cases twenty-four minims of creasote were daily given

in this way for several consecutive days before the growing gastric distress necessitated a diminution of the dose. The figurative thorn upon this therapeutic rose is the bad taste imparted to the milk by the creasote. Some patients do not, however, object to the flavor, and some get on very well by mixing the creasote with only a part of the milk to be taken, reserving the remainder of the milk for the final swallows. In this way the after-taste is greatly diminished, and it may be quite removed by any good mouth-wash.

Rectal injections of milk containing the creasote emulsion, and which the writer has not seen referred to in medical literature, have also proved very valuable in his experience. This channel for the introduction of creasote may be advantageously employed when the stomach or the palate rebels against the administration of the remedy *per os*. One or two drachms of the emulsion, containing, respectively, two and four minims of creasote, may be shaken up with four ounces of milk, and such an enema may be given every five or six hours. When the rectum becomes intolerant of this treatment, a small amount of laudanum may be added to the enema to obtund the sensibility of the bowel, and from two to four drachms of whisky may be added where stimulation is indicated.

Another mode of administration which promises much, but which awaits development, is by means of keratin-coated or other so-called enteric pills. The writer has been thus far disappointed in his efforts at securing pills which would not dissolve in the stomach. The solubility in the gastric juice of those keratin-coated pills which he has employed was proved by eructations of creasote and by the rapid development of gastric irritability. It is, however, quite reasonable to suppose that the pharmacist's art will eventually provide pills or capsules which will resist the action of the gastric juice and liberate the creasote in the intestinal canal, being dissolved by the pancreatic juice and the bile. This part of the digestive tract may thus be made to absorb the creasote when the stomach or the rectum is incapable of its appropriation.

The conclusions reached by the writer, as the result of his reading and of his own experience, are:

1. That intrapulmonary and intratracheal injections of creasote are of doubtful utility, and may be positively injurious.

2. That, for administration by mouth or rectum, solutions and emulsions of creasote are preferable in most cases to capsules, pills, or wafers.

3. That milk is an excellent vehicle for the administration of creasote in solution or in emulsion.

4. That each method of administering creasote used by the writer—viz., by inhalation, by mouth or rectum alone, and by both these channels simultaneously—is useful, and may each be particularly adapted to individual cases. In suitable cases the most rapid progress seems to be made when all these ports of entry are utilized.

5. That the best results for each individual attend the administration of the maximum quantity of creasote which this patient will bear.

6. That the average patient will not easily tolerate more than ten or fifteen minims of creasote *per diem* for any great length of time, and that many will only bear two or three drops *per diem* continuously administered.

7. That it is very important that the treatment be uniform and uninterrupted.

8. That, consequently, an effort should always be made, if intolerance of creasote is shown by any one mucous surface, to employ some other channel of introduction, in order that the continuity of the treatment be not interrupted.

37 East Thirty-third Street.

TENORRHAPHY.

By ELLSWORTH ELIOT, Jr., M. D.,
ASSISTANT SURGEON TO THE VANDERBILT CLINIC AND THE NEW YORK HOSPITAL, OUT-PATIENT DEPARTMENT.

Probably among minor operations few have received the attention that has been given to tenorrhaphy. As a result of this attention, one would naturally infer that the diagnosis and treatment, both operative and subsequent, had reached such a degree of perfection as to demand no further consideration.

But that this is not the actual truth is often brought to our notice by patients who present themselves for treatment of complete or partial loss of function of a member, where a several weeks'-old cicatrix over the course of an important tendon tells too clearly the history of its previous division, as well as the lack, at the same time, of a correct knowledge of the nature of the lesion on the part of the practitioner. But, even with a correct diagnosis, it is not at all infrequent to meet with patients who have submitted to operative treatment in whom the return of the function of the divided tendon can be said to have only partially taken place. Therefore it seems hardly superfluous, even at the risk of repetition, to state and emphasize such principles as should guide us in the diagnosis and treatment of these cases—all the more so, in fact, since frequently the question of the ability of the patients to obtain their livelihood is dependent upon the surgeon's skill in obtaining a good result.

In reaching a positive diagnosis in cases of divided tendon or tendons we are often assisted by considering the character of the weapon that inflicted the injury. From the firm and tough structure of these organs it is evident that blunt instruments or missiles, which produce contused or lacerated wounds of the soft parts, are usually incapable of severing a tendon. In fact, such injuries may tear away the softer tissues that surround a tendon without injuring this structure, or, what is perhaps more usual, may tear away a longitudinal slip from the tendon itself without dividing it.

On the other hand, wounds inflicted by glass or sharp cutting instruments, although apparently "superficial," should always lead to a careful examination on the part of the surgeon. Deficient movement of an injured member by the patient himself is usually a valuable indicator of loss of function of that member. Under certain circumstances it is the only necessary symptom to be elicited. But it is important to remember that, valuable as it is, it is still

capable of misleading one, and that this is especially the case when in the hand, for example, considerable swelling prevents the patient from fully flexing his fingers. Here, even if the long flexor tendon of one of the fingers was divided, the patient would still be able to flex that finger by means of the sublimis digitorum until the large amount of general swelling checked simultaneously the flexion of all the fingers and before the long flexor tendons of those fingers, not the seat of injury, could complete their action in producing full flexion of the third phalanges into the palm of the hand. But, although this swelling prevents the patient from fully bending his normal fingers, yet by the examiner this obstacle may be overcome, with perhaps some pain to the patient, and by him the finger may be fully flexed. With the finger once in this position the patient experiences no difficulty in retaining it there, provided his long flexor tendon is uninjured. If this, however, has been previously divided, the finger, after being forced by the examiner into the fully flexed position, returns with the removal of the examiner's finger into the semi-flexed position, and at the same time the third phalanx becomes fully extended upon the second. But, when more than one tendon is divided, in situations where a considerable number are closely aggregated together, the exact diagnosis becomes more difficult, and usually requires an exploratory incision.

Before resorting to this step, however, we may try another method of diagnosis, especially applicable to those cases in which a number of tendons have been divided—namely, that of electricity. By means of this agent, either with the constant or faradaic current, one pole being placed over some indifferent part of the body, the other over the known point of entrance of the nerve to the muscle, the usual normal reaction will ensue on the passage of the current through the muscle, should the tendon be intact, but would naturally be absent were that structure divided. But this method is open to the objection that a battery is not always at hand, as well as the fact that the exact relations of the so-called "points of nerve stimulation" to the surface of the body vary in different people, and can therefore not be fully relied upon in making an accurate diagnosis.

We come now to the consideration of the most important point of the subject—namely, the treatment of a divided tendon. Tenorrhaphy, like all operations, is one in which the strictest antiseptic precautions should be observed. Billroth says that, in his experience, before the days of antisepsis it was an operation in which septicæmia was not an infrequent sequela. Such an unfavorable termination to-day could only be the result of gross neglect of antiseptic rules.

If possible, the operation should be done with cocaine, because the pain after the primary incision is very slight, and because the patient himself can usually be of assistance in making certain movements of the injured part, and thereby enable the surgeon to detect more readily the tendon for which he is searching. Provided but one tendon is divided, the line of incision should be directly parallel to the line of the tendon, its center being over the point of its division, and the dissection carried to such a point until its sheath is exposed. If, however, several tendons are divided, for example, by a transverse wound in the neighborhood of the wrist, an incision should be made at right angles to the wound, and the crucial flaps so formed should be reflected from the deep fascia, or, in other situations, from that fascia or structure that forms the sheath of the divided tendons, and never through it, for this sheath contains a large number of the vessels that nourish the tendon, and these would be materially damaged by any manipulation resulting in the separation of the sheath from its contents. Also, this same structure sometimes serves the double purpose of sheath and pulley, and in the latter capacity binds the tendon firmly in place and gives it increased leverage in the performance of its function.

Thus the aponeurotic canal which contains the peronæus longus behind the external malleolus not only binds the tendon firmly to the bone, but also helps to serve as a pulley, for here the tendon changes its course and no longer lies in the same vertical line with the fleshy portion of the muscle. Consequently, wherever possible, remove all overlying structures as far as the sheath, through which the divided ends of one or more tendons are easily recognized. The distal end of the tendon is but very slightly retracted; the proximal end, from its being connected to the contracting portion of the muscle, may have retracted a distance of one to even four or five inches, the average being one to two inches. If the distance exceeds this, it will be impossible to draw the divided ends together without opening the sheath of the tendon; but this should always be avoided, if possible, by inserting a very narrow-toothed thumb-forceps within the sheath at the point of division of the tendon, and, after seizing the proximal end, gently drawing it down to the site of suture, where it should be temporarily held by a ligature until the distal end is similarly secured.

Such an extensive incision is also of advantage in making a correct diagnosis. It is not always easy without this assistance, in places where tendons are numerous, to match their divided ends; but if the incision is sufficiently extended toward the origin of the muscle to discover the identity of the proximal stump, that of the distal end may readily be detected by traction, thereby discovering the action of the muscle to which it belongs, and consequently the muscle itself.

It is scarcely necessary to state the great importance of a correct anatomical knowledge of the relation of groups of tendons to one another and to the surrounding parts in enabling one to carry out this step of the operation satisfactorily.

It now remains to consider the different substances by which the tendons which have thus been found divided and the ends of which have been approximated may be held in contact until complete union between them has taken place. Silk, silk-worm gut, and catgut have all been used for this purpose, as well as other material. The first-mentioned substance, however, although known to have become encapsulated in the body, is open to the objection that its subsequent removal from the parts it is made to include takes place by a process of ulceration, and it is reasonable to infer that this cutting through a portion of the tendon must

weaken it, although the divided ends may in the mean time have become healed.

Silk-worm gut, some observers say, has the durability of silk and the capacity for being absorbed that catgut possesses; but that this is not always the case has been the experience of the writer, who has removed stitches of this material from an abdominal wall, after being in place six weeks, when the buried portions were as strong as at the time of their insertion. Catgut, from its undoubted after-absorption, leaves no breach, and therefore does not ultimately weaken the tendon, and also, in virtue of this same characteristic, interferes to the slightest degree with the subsequent healing of the wound by primary intention—a factor upon which ultimate success is greatly dependent. Its durability also is sufficiently lasting for it to accomplish its intended purpose, and, when it eventually softens, the divided ends of a tendon are bound firmly together by the process of union.

With the incisions all ready for suture, one point alone remains to be mentioned. As has already been said, the ultimate success of the operation depends in a measure on securing primary union. In order to render this more certain, the catgut sutures between the tendons may be cut sufficiently long to protrude between the edges of the sutured wound. In this way they serve the purpose of small drains, which carry away all discharge from the neighborhood of the sutured tendons—a region where tension is the highest and, consequently, the risk of suppuration the greatest. By this means the primary dressing may be undisturbed for at least ten days, when, on its removal, all traces of these small drains will have disappeared and, in a good result, primary union will have taken place.

In the application of the dressing it is of paramount importance to fix the limb securely in such a position that the divided tendons will be relaxed and completely at rest. If one or more flexors have been involved, the joint or joints over which the tendons play should be superflexed, and a splint should hold it securely in this position. If the extensors have been involved, the limb should be immobilized, superextended. If two antagonistic groups of muscles have been divided, the limb should be immobilized in that position which represents the resultant action of both groups of tendons.

In the after-treatment the question arises, How soon may the patient begin to use the affected member? a question upon which all are not agreed. In its consideration, however, it is essential to remember that, in the experience of some, tendons which have been sutured have suddenly and without apparent cause ruptured at the point of suture and retracted after an interval of from two to five weeks from the operation. That this accident may occur should tend to make one conservative in the after-treatment of these cases. Too early motion of any kind may be accompanied by this complication. Its delay, on the other hand, does not at all imply loss of function of the member; for it is an every-day matter to immobilize joints for six weeks, or even longer, for fracture or disease, with subsequent full return of function in the part so treated. It simply means an inconvenience to the patient, which had, however, much better be endured than the patient to be troubled during the remainder of his life by a weakness or even a crippling of one of the important parts of the body.

The following case is subjoined to illustrate the method of treatment under discussion, as well as the result obtained thereby:

T. R., nineteen months ago, was admitted into the New York Hospital, suffering from an incised wound just above the left wrist, the result of an explosion of a glass siphon bottle. Examination revealed division of all the tendons on the anterior aspect of the wrist, except those of the flexor profundus digitorum, two of which, however, were nicked; the ulnar artery was divided; the ulnar and median nerves, with the radial artery, were found intact.

Cocaine was injected, and an incision was made at right angles to the incised wound, from its center upward, two inches toward the elbow joint, and the integument and superficial fascia alone reflected, leaving the deep fascia exposed, through which the glistening tendons could be seen. Each one of these was in turn drawn down with a thumb-forceps inserted in the sheath of the tendon to that point at which this structure had previously been divided, and there sutured to its distal portion with catgut, each being joined by one central and two lateral sutures, drawn sufficiently tight to approximate, but not to compress, the ends of the tendon. These sutures were then left hanging from the radial extremity of the wound, the edges of which were brought together by interrupted catgut stitches. An iodoform-bichloride dressing was applied, and the wrist immobilized in the flexed and adducted position. No reaction followed the operation. The dressing was removed in ten days. There was primary union throughout. On the fourteenth day slight passive motion was performed. On the twenty-first day active motion was allowed, and up to the present day the functions of wrist and fingers equal those of the uninjured side.

OBSERVATIONS ON RHEUMATISM, ESPECIALLY AS INVOLVING THE TONSILS.*

By WILLIAM HENRY THAYER, M. D.

Within a very few years different observers have noted the occurrence of rheumatic inflammation in tissues and organs not previously recognized as liable to its invasion.

If we examine all the authorities earlier than 1850, we shall find that acute rheumatism is supposed to affect only the fibrous tissues about the articulations, the voluntary muscles, and the heart, especially its lining and investing membranes.

A little later, some few have recognized its implication of the lungs as a rheumatic bronchitis or pneumonia, its character being revealed by being preceded or followed by articular rheumatism, and yielding to remedies suitable to that disease. Thus Fuller (1852) says that during his service in St. George's Hospital some pulmonary inflammation (bronchitis, pneumonia, or pleurisy) was observed in one in every eighteen cases of acute rheumatism, uncomplicated with recent cardiac mischief. Trousseau in his *Clinical Medicine* says: "There is rheumatic pneumonia," and no-

* Read before the Fifth District Branch of the New York State Medical Association at its sixth annual meeting, May 27, 1890.

where alludes to inflammation of the tonsils. He says, however (vol. i, p. 331): "There is another kind of painful sore throat—the rheumatic sore throat," which he describes as general redness of the pharynx with œdematous uvula, disappearing entirely in a day or two, with metastasis to the articulations. Flint (1879) says: "Bronchitis, pleurisy, and pneumonia are rarely associated with rheumatism." In his *Diseases of the Pharynx* he makes no allusion to any rheumatic inflammation. Garrod (1880) describes rheumatic inflammation of the heart, pleura, and peritonæum, but not of the throat. Watson (1840) and Bennett (1860) make no mention of any pulmonary complication of rheumatism.

The relation of amygdalitis to rheumatism in any case has never been noticed until within a very recent period; no text-book on practice twenty years old has any mention of it. Senator, in von Ziemssen's *Cyclopœdia* (1877), says: "Inflammation of various mucous surfaces is by no means unusual. Foremost among these is bronchitis, then pharyngitis, noticed by Lebert and Meyer." Rheumatic inflammation of the tonsils, such as I shall presently describe as occurring in a number of cases under my observation in the winter of 1888–'89, is either a new manifestation or—which is hard to believe—has entirely escaped notice hitherto. The only experience that has been published is that of Dr. C. W. Haig-Brown, who, in the *British Medical Journal* for September 14, 1889, has a valuable paper entitled Follicular Tonsillitis and its Relations to Rheumatism, in which he relates the frequency of amygdalitis and of rheumatism in a public institution, due, as he thought, to sewer exhalations. Improvement of the sewerage reduced the cases of amygdalitis from twenty-one per cent. of all the sick to five per cent., and rheumatism from four to one per cent. He gives a considerable experience of the sequence of one disease to the other, or their concurrence. He says: "Having so far established a causative and clinical relationship between rheumatism and amygdalitis, we are led to one of certain conclusions: That rheumatism is a general disease, which as frequently finds expression in the throat as in the fibrous and serous membranes; or that the inflamed tonsil is the receptacle for the rheumatic poison, and the medium for its conduction to the general circulation; or, finally, that specific germs find their way into the body under circumstances favorable to their entry, and then evidence their presence in inflammation of the tonsils and the fibrous and fibro-serous membranes."

Garrod says (1880): "The pathology of articular rheumatism must be allowed to be in a very unsettled state, and further observations and experiments are required before we can arrive at any satisfactory conclusion with regard to it. . . . The name implies that the disease has been considered to be dependent upon some altered condition of the blood." This altered condition was believed to be the presence of lactic acid in the blood, the result of imperfect digestion—a belief that originated with Prout. "But," says Garrod, "no abnormal principle has yet been found in the blood; lactic acid has been assumed to exist in it, but no proof has been given of its presence."

The adoption of Prout's view led to the treatment with alkalies, which was eminently successful and considerably shortened the attacks; and it is noticeable that under this treatment the urine after a few days became alkaline, and simultaneously with this change in the urine convalescence began. Acidity somewhere is apparently an element in the pathology of rheumatism, although no acid is found in the blood.

And, says Fuller (1852): "When the rheumatic poison is present in the system, any disturbing circumstance, even of temporary duration, such as over-fatigue, anxiety, grief, or anger, by rendering the system more susceptible of its influence, may prove the accidental or exciting cause of the disease; and exposure to cold or to atmospheric vicissitudes is almost certain to induce an attack. . . . Thus it appears that cold and other external agencies are only predisposing or exciting causes of rheumatism, and that the primary, proximate, or essential cause of the disease is the presence of a morbid matter in the blood, generated in the system as the product of a peculiar malassimilation—of vicious metaphoric action." But what this morbid product is, is thus far only matter of conjecture; neither chemist nor microscopist has been able to discover it.

In the winter of 1888–'89 I saw six cases of rheumatic amygdalitis, some of which are offered in detail:

Case I.—Wilber T., aged twelve, previously well, had an attack of follicular amygdalitis in December, 1888, and on January 14, 1889. On the 24th of January a third attack, with subacute rheumatism, which lasted only four days.

February 10th.—Cough, without physical signs. Pain and tenderness in right groin and along right iliacus internus muscle, and in front of left ear; and on the 12th in the left ankle. Temperature, 100 5° F.; pulse, 102. The dry cough continued till February 17th, the pains having nearly abated, but on the 22d there was still some stiffness of left wrist.

He was then out and going to school until May 23d, when he had an acute amygdalitis, the tonsils being so much swollen as nearly to close the isthmus faucium, with fever. He got an active cathartic, and the next day the tonsils were nearly normal and fever gone. He continued well after this until February 3, 1890, when he had an acute inflammation of the tonsils, with rheumatism, from all of which he recovered in six days.

February 16, 1890.—In bed with subacute rheumatism in toes, ankles, and right hip, which disappeared in two days.

March 12th.—Subacute rheumatism since 9th, now chiefly in left wrist. Slight icterus. Was given dilute nitrohydrochloric acid and strychnine.

14th.—Some pain in cardiac region. Pulse 60, somewhat unequal, with a slight thrill in radial artery.

April 12th.—No pain and no thrill in pulse since March 16th. Out daily and feels well.

Was treated with salicylate of sodium during the several attacks, followed by tincture of chloride of iron and dilute phosphoric acid after convalescence. But the latest attack was treated by nitrohydrochloric acid and strychnine, in addition to the salicylate.

Thus in five consecutive months he had five attacks, and, after nine months' freedom from illness, three more attacks, in the course of two months, of amygdalitis or rheumatism, or both combined. In the intervals he was out and generally at school. Since the latest attack in March he has been well; has been on a plainer diet than usual, with care to avoid anything likely to produce indigestion.

Case II.—A. W. A., commercial traveler, aged forty, married. Has had an attack of alcoholism about every two years; one in October and November, 1888, for which he had been under treatment. Then went to Indiana, whence he returned December 4th with acute rheumatism of arms and neck, amygdalitis and gonorrhœa, dating from December 1st.

December 5th.—In bed. Pulse, 84. Tongue thickly coated. Redness and swelling of tonsils and pharynx, without exudation. Deglutition painful. Neck and shoulders painful and immovable.

7th.—Right knee invaded; neck same. Tonsils pale and less swollen.

In a day or two began to have headache, at first every other afternoon, with fever and delirium. The pain was in the right frontal region. By January 1, 1889, it continued daily, and there was spasm of the left arm and leg when he attempted to rise. The fever recurred every afternoon, and the pain was then most severe. His morning temperature was normal. His knee continued inflamed, but there was no rheumatism elsewhere. The record of January 23d is: "10 A. M., daily headache, generally in the afternoon, with much fever, followed by sweating. Spasm of left side once every day when attempting to sit up, but less severe than it has been. Temperature, 98·4°."

There was gradual improvement from this time until February 1st, when, after the excitment attending an interview about business, he had headache and delirium all day, and in the evening was violent and noisy, until quieted by a hypodermic injection of morphine and atropine. Next morning his pulse was 68; temperature, 98°. The sulphate of quinine, which he had taken since January 23d, was increased January 30th to twenty grains every morning, and ten grains, if fever, every evening. He had no fever or headache after February 2d, and steadily gained strength and flesh. His lame knee was the only remnant of rheumatism, which was gradually relieved under the application of compound tincture of iodine. The quinine was steadily reduced, so that on the 8th of February he was taking six grains a day. On the 9th he was dressed, and began to go to business March 6th. The gonorrhœa never received attention and disappeared in a few days.

The treatment was first with salicylate of sodium, for which acetate of potash was substituted December 9th, and sulphate of morphine and atropine given at night. Quinine was begun December 24th—six grains daily.

January 1st.—Iodide of potassium was given in place of the acetate, and continued till January 23d, when it was omitted, and quinine increased to eighteen grains daily, and bromide of potassium was given with every dose.

30th.—The quinine was increased to thirty grains a day, but reduced after February 2d on the disappearance of the fever.

Case III.—F. B., a girl, seventeen years old, who, March 23, 1889, had an acute catarrh, with cough.

March 27th.—Follicular amygdalitis.

April 5th.—Cough nearly gone. Large swelling, with tenderness of left submaxillary gland, which subsided in a few days.

23d.—Amygdalitis. Rheumatism in shoulders and insteps. Got salicylate of sodium.

28th.—Rheumatism has gone from joint to joint, with little swelling. Now in left wrist only. It soon entirely disappeared.

Case IV.—Miss E. B., aged thirty.

February 13, 1889.—Painful deglutition last two days. Moderate follicular amygdalitis.

14th.—Pain in left arm and in one spot in abdomen.

26th.—Catarrhal laryngitis for two days; still has pain in neck, left chest, and leg.

March 1st.—Cough less. Pain in neck and right side of head.

4th.—Hoarseness and cough much less. Never any expectoration. Pulse, 66; small. No impulse of heart felt. Rhythm normal, except that the first sound is duplicated. Pain at times under right knee; none elsewhere.

6th.—Pain in both ankles and right elbow. Got out about March 12th, and lameness of joints gradually disappeared.

Case V. *June 3, 1889.*—Grace W., aged sixteen. In bed with acute articular rheumatism, involving now left knee and ankle and lumbar region. Has had this for several days, following quinsy with purulent discharge. Reports that she had quinsy in 1886 and 1888, the second attack being followed by articular rheumatism, continuing nine weeks.

5th.—Right hand swollen and very painful; no rheumatism elsewhere, except at times pain in the left chest, with dyspnœa. Pulse regular. Impulse of heart normal.

7th.—After visit on 5th, the left hand became inflamed. Yesterday both hands were well. Last night and now, some pain in chest, due to indigestion. Relieved by a mustard emetic, and had no return of rheumatism.

Case VI.—Mrs. C., aged thirty.

February 3, 1889.—Follicular amygdalitis, with subacute rheumatism.

Case VII is of especial interest, as an instance of rheumatism involving a derangement of the lymphatics. E. K., a generally healthy boy, twelve years of age, began late in November, 1889, to have occasional pain in the left side of the abdomen, over a limited region, without fever or other symptom. Then headache for several days. But by December 4th his pains were gone and he went to school.

December 12th.—Pain in the right side of abdomen between the crest of the ilium and the ribs when he moves, and somewhat aggravated by pressure. None on the left side, none in head, some pain in left tonsil. Is generally well.

16th.—Slight pain on both sides of abdomen. The left submaxillary lymphatic gland has been swollen and tender for the last two days.

He had slight fever December 21st and 22d. Temperature, 100·8°. From that time through January he had daily moderate headache from rising until noon, and every day slight pain in abdomen, but he was not far from well in general, did not lose flesh, and went to school daily.

January 25th.—Pulse, 84, regular. Temperature, 98·8°. Slight pain on both sides of abdomen and lower right chest, without tenderness. Bowels moving daily. Swelling of lymphatic submaxillary gland nearly gone. From this time he was taken out of school, but was out of doors daily. He continued to have slight pains a part of every day—sometimes on one side, sometimes on the other of abdomen and chest; but by the middle of March they were much less frequent. He had a good appetite and slept well.

March 21st.—Yesterday began to have some sore throat, but so slight that he did not speak of it. Was feverish and restless all night. This morning great swelling of the left (salivary) submaxillary and sublingual glands and surrounding tissues above and below lower jaw, so that he can only separate jaws half an inch. Face flushed. Swallowing painful. Pulse, 120.

5 P. M.—Opened mouth with difficulty widely enough to show swelling of entire soft palate and tongue; not very red.

22d.—Raises some mucus, streaked with blood. Pulse, 114, less full.

5 P. M.—Pulse, 100. Temperature in axilla, 100·8°. Some headache.

He improved rapidly, but on March 30th was still somewhat restricted in opening his mouth, by the relics of the cellu-

litis around the muscles of the jaw. He had no abdominal pain during this attack, and has had non eanywhere since his recovery, eight weeks before the date of the present report. About the first of May he had an indigestion, entirely relieved by a mustard emetic.

Seen May 7th. Feels very well. Left lymphatic submaxillary gland still visible and palpable, bnt not tender.

His treatment was first with a cathartic, then salol for a fortnight. Then iron, quinine, and phosphoric acid. The attack of cellulitis was treated with a cathartic dose of calomel, aconite during the continuance of the fever, with a mouth-wash of carbolic-acid solution, and soap liniment and aconite liniment to the cheek, with whisky after the first day. And when convalescence was fairly established he was put upon dilnte nitrohydrochloric acid after meals, which was continued four weeks.

May 22d.—Two months from the attack of cellulitis. During this interval he has been entirely free from pain or other symptom, except the attack of indigestion mentioned at the beginning of the month. To-day there is slight swelling and tenderness of the left parotid gland, with some pain in chewing. Throat normal. No pain in swallowing. Tongue clean. No fever.

Directed decolorized tincture of iodine to the surface three times a day, and an aloetic laxative.

23d.—Swelling less; hardly any tenderness. No pain in chewing. Reports slight pain on right side in swallowing. Tonsils nearly normal size. Tongue clean. Temperature, 98·8°. Pulse has a slight thrill; impulse of heart strong, regnlar. Feels well. Goes ont.

Solution of carbolic acid and glycerin for gargle.

25th.—No pain in swallowing. Parotid swelling has nearly disappeared, but there is a slight swelling and tenderness of integuments arounnd zygomatic arch.

Resume dilute nitrohydrochloric acid.

There has been through this case evidence of the endocardium sharing in the rheumatic affection, indicated by a somewhat rasping systolic sound and a thrill in the radial pulse at the time of the acute attacks. He had never previously to this illness had any cardiac affection.

Some of the cases just related may be a desirable contribution to the study of the physiology of the tonsils which has enlisted the attention of various physicians within the last few years. Without venturing to express any opinion upon the subject, I offer them as possibly available items of evidence when the physiological inquiry is in progress. It was begun, I believe, by Dr. R. Hingston Fox, and has been pursued by Dr. S. Spicer and several others, but never experimentally. Dr. Fox says of the functions of the tonsils in health (*Lancet*, 1888): "These organs consist of a mass of closed sacs or nodules, identical in structure with those of the solitary and Peyer's glands, and, indeed, of the ordinary lymphatic glands of the body. Some small mucous glands open into the crypts on the surface, but these are quite insignificant. . . . Their functions must be of the absorbent kind. . . . In health, food matter, perhaps a ferment, would be absorbed from the saliva, and stimulate the tonsils to healthy activity. In disease a poison, perhaps also a ferment, is absorbed from the saliva and overstimulates the tonsil; there is overactivity, multiplication of ill-formed cells, and other phenomena of inflammation."

Dr. Spicer (*Lancet*, 1888), quoting Dr. Fox, says the tonsils are absorbents of the excess of buccal secretions and liquids from the food, and form part of the blood-manufacturing system—"nurseries for young leucocytes, planted by the waterside, and drawing their sustenance from the nutrient stream. . . . The anatomical facts on which these views are based are the following: The tonsils are like sponges in texture, consistence, and structure, being riddled with lacunæ or crypts. In the intervals of deglutition these spongy organs lie in the glosso-epiglottic fossæ, soaking in the buccal secretions, which fill up all their pores. Further, the tonsils are constructed on the type of a mucous membrane, corrugated so as to expose a large surface, and on these corrugations are thickly studded lymph follicles, as well as in these organs a very rich plexus of lymphatic vessels, which must have some function; and what more probable than the relation suggested, of which we have so much confirmatory evidence. Also these follicle aggregations are situated at places just below the output of the buccal secretions, and in the course which these must take."

It will be observed that the views just quoted of the physiology of the tonsils are purely theoretical. They are plausible theories, but careful experiments which have been made lately do not confirm them. Dr. Eugene Hodenpyl, of Brooklyn, has been devoting much time and care to experiments upon living animals and microscopic examination of the faucial tonsils, with results not yet published, but which he has kindly permitted me to use. Some of his conclusions from an exhaustive study of the tonsils are as follows: "None of the theories thus far advanced to explain the functions of the tonsils are conclusive. The tonsils are not absorbing organs. They neither absorb fluids nor solid particles from the mouth, under ordinary conditions, nor do they take up foreign materials from the tissues in their immediate neighborhood."

The question as to the office of the tonsils in health, and what relation they bear to the general physical organization in the diseases in which they suffer, may be considered to be still open for investigation and discussion.

Antiseptic Solutions for Midwives.—"The Académie de médecine, of Paris, having recommended that midwives should be advised to employ a solution of bichloride of mercury in all obstetric cases, and that to avoid accidents it should be colored, a committee, including MM. Brouardel and Tarnier, and of which Dr. Baden is the reporter, recommends that the packets of disinfectant should be made up according to the following formula: 'Corrosive sublimate, 25 centigrammes; tartaric acid, 1 gramme; alcoholic solution of dry carmin of indigo (5 per cent.), 1 drop; reduce to an impalpable powder.' This quantity suffices for a quart of water."—*British Medical Journal.*

Death after the Inhalation of Bromide of Ethyl.—"A somewhat important case is now before the Berlin courts, in which a dentist is charged with having caused the death of a patient by means of an anæsthetic. The patient was a lady, and the dentist intrusted his pupil, whose age was under seventeen, with the administration of bromide of ethyl. Of this about an ounce was administered, together with four or five drops of chloroform. The patient is stated to have recovered completely from the effects of the anæsthetic, and to have felt quite well during the remainder of the day. The next day, however, she died, and a commission of medical experts has been directed to report upon the matter."—*Lancet.*

SOME POINTS IN THE DIAGNOSIS OF CERTAIN SIMULATED MENTAL AND NERVOUS DISEASES.*

By J. T. ESKRIDGE, M. D.,
DENVER, COL.,
FORMERLY POST-GRADUATE INSTRUCTOR IN NERVOUS DISEASES IN THE JEFFERSON MEDICAL COLLEGE, AND PHYSICIAN TO THE HOSPITAL OF THE COLLEGE, ETC.

The symptoms exhibited by a shrewd malingerer or a clever hysterical patient may so closely simulate organic disease of the nervous system that the best diagnostician will at times hesitate in some cases before giving an opinion. In some instances persons suffering from actual disease of the nervous system may feign, for reasons best known to themselves, a different trouble, or the hysterical may simulate a certain organic nervous affection and at the same time be suffering from some other organic disease; and, on the other hand, we not infrequently find an array of so-called hysterical phenomena in patients who are afflicted with some serious organic brain lesions. The hysterical should not be confounded with the malingerer, but it is rarely we see a case of hysteria without some elements of malingering. The causes for the latter are different from those that result in hysteria.

Malingering.—In civil life the causes for malingering are found among the mercenary, who feign injury for the hope of gaining remuneration, from a corporation most commonly; among the criminal class, who hope to escape their deserved punishment; and among the tramp class, who are trying to "dead-beat" their way, in order to gain sustenance in hospitals, or to eke out a miserable existence by imposing upon the charitably inclined. Among the criminals and tramps epilepsy and insanity, according to the writer's experience, are the most common affections of the nervous system feigned; but among the mercenary feigners organic diseases of the spinal cord, and sometimes of the brain, are more or less imperfectly simulated.

The object of this paper is not to go into a lengthy discussion on the points in the differential diagnosis between real and feigned disease, but to call the attention of the members of the society to the subject of the paper in the hope of eliciting discussion and the narration of similar cases. I will illustrate the tramp, criminal, and mercenary malingerers by the following:

Tramp Class. Case I. *Feigned Epilepsy.*—A boy, eighteen years old, gave a history of convulsions dating over a period of three or four years. He professed to be a telegraph operator. He was found on the streets of Denver in a convulsion, and taken to a police station in an apparently unconscious condition. He was taken to the County Hospital the next day. He was having, on an average, two or three convulsions daily, but none of the attacks since his admission into the hospital had been witnessed by a physician. He was given large doses of sodium bromide, but his attacks continued and seemed to increase in frequency. This fact was reported to me and at once aroused my suspicion of their genuineness. On further inquiry, I found he did not bite his tongue, and that the attacks usually only occurred in the presence of certain persons whose sympathies he had enlisted in his favor. On getting a detailed history from him of his attacks, I found his mental condition at the time of their occurrence and the seizures themselves did not correspond with the phenomena of epilepsy. I requested Dr. Baker, the resident physician, to have the nurses or attendants notify him of the attacks, and for him to study them. At my next visit the doctor reported that he had seen an attack in which the patient assumed grotesque positions, and that the eyes turned upward when he raised the lids to examine the pupils. I immediately had his bromide discontinued, and gave him, instead, large doses of milk of asafœtida by the mouth. He protested that he had no control over his seizures. Not long after this I witnessed one of his attacks. He frothed at the mouth, threw his limbs in every conceivable direction, and assumed an opisthotonic position. At this stage I made firm pressure over each supra-orbital nerve with the ball of each of my thumbs, and, as the pressure increased, it caused him so much pain that he struggled to free himself from my grasp, and caught hold of my hands and pulled them away from his face. On my again renewing the pressure, and this time with redoubled energy, he jumped up, and the spasm (?) was over. From this time he took the precaution to have no more convulsions when a physician was around. Only a few attacks occurred during the remaining weeks of his stay in the hospital, and these were always in the presence of persons whose sympathy he had enlisted in his favor. A few days after he was dismissed from the hospital he was again found by the police lying on the street in an apparently unconscious condition. He was returned to us for treatment. This time, from the first, he was treated as "a suspect," and denied many privileges of the hospital which the other patients enjoyed. No bromide was given him. He had a few attacks at chosen intervals, but these always occurred in the presence of certain persons, and away from the presence of the attending physician. After remaining at the hospital for a few days, he suddenly left to escape arrest for theft.

Case II.—An inmate of the hospital for one or two years, about forty years old, says that he has been subject to epileptic convulsions for three or four years, the attacks dating from the time when his left knee, which is now ankylosed, first became affected. The patient is addicted to drunkenness, is disagreeable, quarrelsome, repulsive, and believed to be a masturbator. I first began to study his case in November, 1889. At that time he was taking large doses of potassium bromide, and was reported to be having one or two attacks during the day, and at times as many as three during the night. The night in November immediately preceding my seeing him he had had several seizures, and had kept the patients in his ward awake most of the time. Two or three persons had been engaged in holding him. I saw him about 4 P. M. He was then in an attack, and the nurse stated that he had had them almost continuously for hours. His face was flushed, and his movements were an admirable imitation of an epileptic attack. I had never suspected the genuineness of his malady, and now supposed he was in a condition of status epilepticus. On inquiry, however, I learned that he would sometimes throw himself from the bed in an attack and thrash himself around the room at a furious rate unless restrained. On raising the eyelids the eyes turned upward and the pupils reacted to light. The pulse was not much accelerated above the normal. I immediately made firm pressure over each supra-orbital nerve; the convulsive movements stopped, and the patient expressed his surprise by a silly laugh. He then admitted that he had been feigning "fits," but contended that he was subject to regular epileptic paroxysms. I had the bromide discontinued, and no convulsions occurred for several

* Read before the Colorado State Medical Society at its annual meeting.

days. In a short time the nurse reported that he was again occasionally having a convulsion, but I did not have the good fortune to witness any more attacks, and Dr. Baker, the resident physician, said he had not seen any of them. He was urgent for medicine for his epilepsy. I ordered twenty grains of sodium chloride to be given him three times daily. As the medicine tasted salty, but different from his usual bromide mixture, he thought it was composed of potassium bromide and iodide, and again his paroxysms ceased, and have recurred only a comparatively few times since. At the present writing he has not had a convulsion for nearly ten weeks. I have a suspicion that this man may have true epilepsy, with a large element of "pure cussedness." On one occasion, Dr. Baker informed me, he acted strangely in a dazed kind of manner, and afterward seemed to have no recollection of what he had done during this time.

Criminal Class. Case I.—In the spring of last year a man by the name of T., whose paramour, with whom he had lived for ten years, claiming her as his wife, left him and became intimate with a man by the name of K. T. threatened to kill K. and the so-called Mrs. T., and purchased ten grains of strychnine at a drug-store in the name of K. T. soon left Denver and went to Omaha. A few weeks later T. arrived in Denver about four o'clock, P. M., and secreted himself until dark, when he went to the rear of the house in which K. and Mrs. T. were staying. He there met K. and fatally shot him. He remained in the city twenty-four hours and escaped to Kansas City. He was arrested and brought back to Denver. At the trial, at which he was convicted of murder in the first degree and sentenced to be hanged, he gave me the details of the killing, the causes that led to it, and many of the particulars quite connectedly. He is a man below the average intelligence, but cunning, and shows an infatuation for his unworthy paramour. There certainly was no evidence of insanity, and I so testified. A short time after T. was removed to the State Penitentiary at Cañon City he was alleged to be insane. He was brought to Denver early in the fall of 1889—this time in order to have the question of his insanity tested. He then professed to have forgotten almost everything; he had never heard of a man by the name of K.; never heard of a place called Denver; never knew that he had been tried for killing any one; did not know where he had been staying. He gave expressions to delusions of depression and expansion at one and the same time. He at times very feebly and imperfectly imitated the paretic dement, but usually best played the rôle of a dement. This was done so poorly as to expose the deception to any one at all conversant with mental diseases. He feigned to have forgotten everything connected with the past—especially everything connected with his crime, things that stamp themselves almost indelibly upon a mind capable of remembering anything. But, at the same time, he could relate what was given him to eat, how he was treated, and little occurrences in prison life. This man is still in the State Penitentiary, and is alleged by some to be insane.

The diagnostic points in this case are: First, the character of the delusions. No one, sane or insane, can be depressed and animated at one and the same time. An insane person can not have delusions of expansion (mania) and depression (melancholia) at one and the same time. Such delusions may alternate, but there is always a change in the person's actions while possessed of an expansive or depressed delusion.

Second, as regards memory: In dementia, memory of past events is always retained after memory of recent events have faded away.

Case II.—A male criminal, about thirty years old, was confined in the Arapahoe County jail, accused of obtaining money under false pretenses. He had been incarcerated for several months, and seemed to be in fair health. About four weeks before the time set for his trial he began to have convulsive paroxysms. These continued for three weeks, although he was taking large doses of potassium bromide. The attendants at the jail were up with him night and day, two or three being required, they thought, to prevent his injuring himself against the iron bars, as he threw himself about at a violent rate. Dr. McLauthlin, the county physician, had seen him a number of times and pronounced the attacks hysterical or feigned. He requested me to see him. I visited him early one morning, found him strapped down and three attendants by him. They stated that he had been having convulsions every few minutes all night, and that it was with great difficulty that they could prevent him from injuring himself. His pulse was 110; breathing rapid; temperature normal. His face was pale and haggard. While I was talking with him he said: "Now it is coming again," and began to roll his eyes upward. His face was twisted from side to side, not spasmodically jerked by individual muscles. Soon his arms and legs were involved and he assumed an opisthotonic position. I spoke to him; he neither answered nor gave the least sign of hearing. I opened the eyes and found the pupils reacted to light. Without further examination I placed the balls of my thumbs over the supra-orbital nerves at the point of their emergence from their foramina, and pressed with considerable force. The result was marked and almost instantaneous. He at once endeavored to turn his head from me, but, failing in this, he clinched my hands with both of his and pulled, and at the same time freed his head from my grasp by a voluntary rotation of his head. I requested the attendants to leave the cell. I then told the prisoner that I had caught him feigning, and that if he had another such spell while he was in jail I would go into Court, if called upon to testify in his case, and swear that he was feigning, which would prejudice the jury's mind against him. He promised to desist from another attempt. I had him unstrapped and dismissed his attendants, assuring them that he had no further need of their services. His epilepsy was cured. His object in feigning epilepsy was to be transferred to the County Hospital for treatment, from which he knew he could effect his escape.

Mercenary Class. Case I.—Miss O. fell, in stepping from the car of the Denver Tramway Company in January, 1889, striking the back of her head against the ground. She seemed to be dazed or semi-unconscious, and was taken into a house a few yards distant, where she remained in about the same condition until transferred to Saint Luke's Hospital the next morning. She was in the hospital two to three weeks, and about one week of this time she seemed to be semi-unconscious, but irritable and cranky all of the time. It was learned that there was some bruising of the soft tissues over the occipital bone just to the left of the prominence of this bone. It was thought by the surgeon under whose care she was at the time she remained at the hospital that there was a fracture of the occipital bone, with depression of the fracture.

By order of the Court, Dr. H. A. Lemen, Dr. H. A. Baker, and the writer were appointed to examine into her condition, The examination took place October 17, 1889. Her history, as she gave it to us, was as follows: She said she had always enjoyed good health up to the time of the accident, but since that time she had lost just forty pounds by actual weight; she had grown nervous; suffered much from pains in the back and head, especially in the occipital region; was sleepless; could not see the largest letters on the street signs, and it was with great difficulty that she could walk. We found her temperature, includ-

ing that of the surface of the head, normal. The motorial and sensory phenomena showed no deviation from health. The electrical reactions and reflexes, deep and superficial, were good and equal on both sides. Touch, taste, smell, and hearing were well preserved and about equal on both sides. We now came to the eyes. She contended that before the accident she could read fine print and signs at a distance, as well as the ordinary person, without the use of glasses. We found the pupils equal, reacting well to light and accommodation, and about normal in size. The ophthalmoscope showed healthy fundi. The fields seemed contracted, but, on repeating the examination several times, the size of the fields varied very considerably. She was shown a book and professed to be unable to see whether or not there was any print in it. Of large letters, which the normal eye will read at a hundred feet distance, she said she could not see what they were when held only a few feet from her eyes. Glasses, plus 36, about one dioptre, were placed before each eye. She then read fine print at the ordinary distance. The fields of vision were enlarged, and she read at a distance as well as the majority of persons. This was positive proof that she was feigning poor vision. As we had found no evidence of any organic disease, we felt justified in excluding any, especially after detecting her in feigning imperfect vision. She was nervous, irritable, and not very well nourished. After excluding everything except spinal irritation, we next proceeded to test the truthfulness of her statements regarding her health before the accident. We weighed her and found that she was nearly ten pounds heavier than she professed to have been two days before her examination. Upon inquiry of her employer at the time of and before the accident, we learned that she had not been well. He said that she looked as well in October as she did in January before the accident, and that while she was living in his family she had been nervous, irritable, and poorly nourished, and required to rest in bed one day every week or two on account of pain in the lower portion of the body. The physicians who had treated her before she came to Colorado stated that she was irritable and nervous, and suffered from uterine trouble while under their care. Since our official report we have seen her on the streets of Denver walking as briskly and nimbly as one in perfect health.

Case II.—Mrs. H., aged thirty-three, was a passenger on the Santa Fé train at the time of the Fountain explosion from giant powder in May, 1888. Her face and hands were cut with glass, and she was shaken up considerably. The explosion took place about 4 o'clock, A. M., while the passengers were all asleep. She stated that before the accident she had enjoyed perfect health, but since that time she has been nervous and sleepless, and has suffered from pain in the head and spine. She has brought suit against the railroad, and, as with most persons who are waiting the award for damages, every symptom is exaggerated. The first examination, in August, 1889, was highly unsatisfactory, as she complained of the slightest contact of substances with any portion of the body. After a prolonged examination I could find no evidence of any organic trouble, and so informed her. She presented herself a few months ago, and still no symptoms of any organic lesion were found. On May 16, 1890, she again presented herself for examination, with the following account of her symptoms: She says she has constant pain from the middle of the back, running through to the stomach; has great difficulty in rising from the sitting to the erect posture on account of pain in the back. The pain in the back runs from below upward. Complains of pain and a drawing sensation in the legs and feet at night. She is exceedingly nervous and feels as if something was going to happen. Says she is unable to read fine print, and a bright light is painful; is deaf in the left ear, and can hear only imperfectly with the right. Says that conversation carried on in an ordinary tone of voice she does not hear; complains of buzzing in the head and a dizzy sensation, a feeling likened to lumps in the back of the neck, and a drawing sensation of the post-cervical muscles, causing her to bend her head backward.

Examination.—Gait good; no ataxic symptoms; knee-jerks equal, but slightly exaggerated. All the other deep reflexes normal, as are the superficial reflexes. A thorough and prolonged electric test, both with galvanism and faradism, showed normal reactions. The results of testing the sense of touch were curious and significant. Some time was spent in trying to ascertain the condition of this sense. At one time it was normal; the next minute it would vary greatly from the normal, or she would profess not to be able to feel anything. There was no paresis, paralysis, or wasting of any muscles. She was able to bend the back in various positions without complaint if her attention was kept engaged, but her movements became limited and painful when her attention was directed to what she was doing.

The dynamometer registered R. 80; L. 80. On requesting her to try the instrument again, it registered, only a few minutes after the first trial, R. 110; L. 104.

The examination of the special senses was not completed when I had to postpone it until the next day. As yet, two weeks having elapsed, she has not presented herself.*

Whatever real trouble the outcome of this case may result in, it is now evident that she is hysterical and feigning, and thus, by her over-anxiety to appear injured, she may be preventing the detection of some organic lesion.

Case III.—Mr. M., a nervous, slenderly built man, about forty-five years old, was injured on the Denver Tramway Road by being struck on the back by a wagon while in the act of getting on a car. He was knocked down and rendered unconscious for some hours. He remained in bed about a week. About six months after the accident Dr. Parkhill and I examined him at his request, for the purpose of testifying in court. He professed to have considerable pain in the back throughout the entire length of the spine. He complained of the slightest touch on most of the spinous processes. He had a limping, halting gait, walked with a cane, and said he had most pain in the lower portion of the back and in the left leg. After two prolonged and thorough examinations we found movement much more free and extensive than he had stated. Sensation in every portion of the body was normal. The reflexes and electrical reactions showed no deviation from health. We could find no positive evidence of any organic lesion, and one of us, the other not being called, so testified in court.

In conclusion, I will discuss only a few of the points suggested by the case histories that form the foundation of this communication to the society:

First, the detection of feigned epileptic convulsions. Under ordinary circumstances, the dilatation and immobile state of the pupils, the insensibility of the corneæ, the character of the muscular contractions, the onset of the attack, the stages of the seizure, and the subsequent sequelæ will serve to distinguish the true epileptoid or epileptic fit from the feigned. But we must remember, as Romberg long ago pointed out, that there may be some reflex irritability in true epilepsy, such as to produce winking when the cornea is touched. During the past year I saw an account of the observations of a German physician, whose name I have forgotten, on the detection of feigned epilepsy in crimi-

* Her suit has since been decided in the U. S. District Court. She sued for $25,000, and was awarded $750 damages.

nals. This observer had detected simulated epilepsy in several hundred criminals simply by pressing with the ball of each thumb over the supra-orbital nerves. His position is behind or at the head of the "suspect," with his face looking toward the simulator's feet. In this position one can exert considerable pressure on the supra-orbital nerves, and if the patient is not unconscious he is unable to bear the pain, and soon endeavors to free himself from the operator's grasp. I have not had the opportunity to try this test in attacks of true epilepsy, but here a corrugation of the forehead would not be sufficient to pronounce the case feigned, because there may be some reflex action of the muscles even when a person is unconscious. I have had the opportunity of employing this method in detecting feigned epilepsy in four malingerers, and in each the attack was cut short, and the simulator exerted himself voluntarily in order to get relief from the pressure.

Before leaving the subject of feigned epilepsy I wish to utter a caution—viz., that because a person is caught feigning epilepsy we must not at once conclude that he does not suffer from real epilepsy. Real and feigned epilepsy, I think, were exhibited by at least one of the persons whose cases have just been narrated.

Feigned Insanity.—In the majority of cases of simulated insanity the deception is comparatively easy to expose. It is self-evident that the task is made easy in proportion to the familiarity of the examiner with the different types of insanity and their differential diagnosis, and in proportion to the amount of clinical study he has given to the insane. It sometimes happens that an asylum superintendent is a poor diagnostician of insanity, because, in many instances, of the large amount of executive work devolving upon him, thus leaving him insufficient time to devote to the intelligent and systematic study of minute peculiarities of individual cases and groups of cases. It is rarely that a simulator of insanity is sufficiently informed in regard to the diagnostic symptoms of the different varieties of the disease to prevent his confounding them. His task is especially difficult when he attempts to simulate mania, melancholia, or dementia. In mania or melancholia the patient may be boisterous or quiet, but in the former the delusions are always of an expansive character, while in the latter they always take a depressive form. In dementia, a form of insanity probably one of the most difficult to feign, the failure of memory is just the opposite to what the ordinary layman, when he attempts to simulate, will assume. In this form of insanity memory for recent events is first lost or affected, while that for occurrences which took place before the mind became impaired is often retained with great minuteness for details; and this holds good until the mind becomes almost a total blank. The patient is usually quite talkative unless harassed by depressive delusions. Recent events, unless of an extraordinary character, make no or but little impression. He is unable to tell what occurred the day before, or what he ate the previous or probably the same day. Any one who has studied the diagnostic symptoms of dementia and is at all conversant with the symptoms exhibited by T. must realize that by deception this criminal has thus far cheated justice.

In stuporous insanity malingering is sometimes hard to detect. A case of feigned stupor reported by Field in the *New York Medical Journal* for May 3, 1890, will illustrate this:

"Since his admission he had not spoken or made any voluntary movement; would follow where he was led; if put in a chair, would remain there; would not partake of any food or water unless they were put in his mouth; would swallow mechanically. Sometimes he would wet his clothing or the bed. He had a fixed, staring expression, only occasionally winking. He was not cataleptic, although two physicians had so certified to the District Attorney. Nothing would startle him out of his condition—neither pricking, nor dashes of cold water, nor pressure on the supra-orbital nerves. He lost thirty to forty pounds of weight. Subsequently he was sent to the Jefferson Market prison, from which he escaped by sawing out a bar in conjunction with another prisoner. His associate was recaptured and told how he had aided the malingerer in his deception. The feigning of the prisoner had been carried on for three or four months."

Real or Pretended Traumatic Cerebro spinal Affections, especially such as follow Railroad Accidents.—That cases of severe and permanently disabling nervous injuries follow upon and are caused by the physical and mental strain incident to severe railroad collisions are as well attested as that cases claiming such injuries have been suddenly and permanently cured after damages for the same have been settled by the company sued. In the few remaining minutes for which I crave the society's indulgence I shall not attempt to discuss the positions taken by three classes of writers on the so-called "cerebro-spinal shock." One class, represented by the railroad surgeon, who often becomes in these suits for damages railroad advocates, contend that most of the symptoms are simulated. The second class is formed by Charcot and his disciples, who at one time maintained that all of the symptoms might be accounted for on the theory of hysteria, especially the class which he designates traumatic hysteria. And the third and last class is composed of the over-enthusiastic so-called medical expert, who is too apt to accept the statements of the patient implicitly and attribute all of the symptoms to some obscure organic disease of the nervous system. Practically we meet with applicants for remuneration the symptoms of whose injuries are mostly, if not entirely, feigned; and others whose ailments are purely of an hysterical nature, and yet others whose symptoms are due to organic disease of the nervous system. On the other hand, it is not infrequently that we may find the simulated, the hysterical, and the organic symptoms combined in the same patient at the same time.

We may ask, What should be the testimony of the medical witness when called upon to testify in regard to nervous injuries, real or feigned, alleged by parties suing for damages? He should be unbiased, and base his testimony on demonstrable facts and not upon possibilities. It is well to bear in mind that the central nervous system may have sustained permanent injuries and no objective symptoms be manifest to the most careful examiner until several months, or perhaps one or more years, after the accident.

This should teach the claimant caution. In such cases, if the patient's health is not being injured by delay of legal proceedings, the suit should be deferred as long as possible. The examinations should be made jointly by at least two physicians—one for the plaintiff and the other for the defendant—and these should consult together simply to arrive at the truth. The examinations should be thorough, and repeated sufficiently often to prevent erroneous conclusions. The patient's body should be bared, the spines of the vertebræ and the muscles of the back carefully examined—the former for tenderness and deformity, and the latter for tenseness or rigidity. We should look for wasting of muscles. Next, the patient should be required to bend the back in different positions, and the freedom or restraint of motions observed and carefully noted. The gait of the patient should be scrutinized, and all of the tests for ataxic symptoms carefully employed. The reflexes, deep and superficial, should be thoroughly investigated, after which a careful electrical test for the condition of the nerves and muscles should be used. The tactile, muscular, temperature, weight, and pain senses should be carefully examined and compared on the two sides of the body. This is sometimes of the greatest importance, especially when hysteria or feigning is suspected. I have some cases of organic lesion of the cord under my care at present in which, in certain portions of the body where the senses of touch and pain are present, the sense of temperature is abolished. There should never be less than two thorough examinations, and the results of the second examination should be compared with the first. The condition of the special senses should never be neglected. The patient's own story of his sufferings should be duly considered, but only in connection with the results of the examination. In other words, we should never be led into the error in these cases, where heavy damages are claimed, of making a diagnosis on subjective symptoms only, as has occurred in a recent case in this city. The health of the patient prior to the accident should be ascertained, if possible. If, after careful and repeated examinations, we find no objective evidence of disease of the nervous system, it seems to me that the only thing left for the medical witness to do is to so testify; for, if we have to base the diagnosis entirely on subjective symptoms, unaided by physical signs, we are placing the companies sued, so far as our testimony is concerned, on the honesty of the claimant for damages. Some of our courts of this city have decided, and it seems to me properly, that if the medical man has to base his opinion of the case entirely upon what the patient tells him, such testimony in those cases is inadmissible, and the claimant's statements must go direct to the jury without being interpreted for them by a physician.

I wish to say, in conclusion, that the physician who has carefully studied these cases and compared the results of different examinations will soon be able to sift the truth from the feigned symptoms of disease. Especially is this true when the physiognomy of the patient is studied during the examination and compared with its appearance when his attention is not absorbed by the examiner's method of procedure.

AN INQUIRY INTO THE RELATIONSHIP OF AMYGDALITIS TO THE CEREBRO-SPINAL CENTERS.

By J. RICHARDSON PARKE, Ph.G., M.D.

Lesions of the buccal and guttural mucous membrane and its underlying structures, especially acute suppurative amygdalitis, by reason both of their frequency and extremely painful character, challenge to-day no insignificant share of the practitioner's attention, and warrant, I trust, the public expression of whatever opinions experience or observation may dictate in reference both to cause and treatment.

When we remember the anatomy and physiology of the tonsils, both of which are admirably set forth in the Lancet for 1888, ii, 805–807, by Spicer, the tenuity of the follicles which comprise the gland, the character of secretion, and the intimate manner in which it stands related to both great divisions of the nervous system, comparing their somewhat unique physiology with the remarks which every physician must sometimes hear in reference to certain peculiar phenomena attending the onset of the disease, I can not but wonder that the attention of pathologists has not been directed more specifically to the question of idiopathic neurotic influence in the causation of this exceedingly prevalent and painful complaint.

Most common in young strumous constitutions, which it is well known are usually of high-strung nervous temperaments, it has hitherto been supposed, even by such close observers as Ringer, Cornil and Ranvier, and the late Professor Gross, to be dependent upon such trivial causes as cold, exposure, etc., without even an inquiry into the remarkable fact that similar exposure will *invariably* produce in one amygdalitis, and in another *always* pharyngitis and *never* amygdalitis; in one the slow, deliberate changes of a typical membranous inflammation, in the other a rapidly developing suppurative cellulitis.

That the disease is not induced primarily in insusceptible subjects by either cold or exposure is proved by a thousand facts within our knowledge. Some of our old army surgeons who witnessed the horrible exposure of our soldiers on some of the Southern battle-fields, as well as the Surgeon-General's Reports, speak of comparatively few cases of tonsillitis, while tetanus, sciatica, and other neuroses were exceedingly prevalent.

After the battle of Ticonderoga in 1758 the wounded were exposed all night in open boats on Lake George. Nine died of traumatic tetanus; *no* cases of amygdalitis. On board the frigate Amazon before Charleston, in our war with the British, similar reports are recorded. The battles of Bautzen and Dresden in Napoleon's third campaign, and a thousand others in history, furnish similar instances (Gross). Amygdalitis is uncommon to the higher types of virility, but occurs chiefly in anæmic, delicate girls, and in men sometimes when the nervous system is unstrung by excesses, either sexual or alcoholic. A patient of mine, a mill girl, having no exposure to cold, developed acute amygdalitis four hours after being struck in the back by a loose belt; and while practicing in Philadelphia I treated a case of sup-

purated tonsils *palpably* induced by reading the newspaper details of a fire on Pine Street, where two people were roasted to death. The lady had never left her comfortable room, yet the onset of the disease occurred within *three hours* after reading the horrible details.

The glosso-pharyngeal nerve rising from the gray nuclei in the floor of the fourth ventricle is very closely connected with the pneumogastric, sympathetic, and facial nerves, and at the superior cervical ganglion it touches like the key of a battery the whole sympathetic system, both giving and receiving impressions, and, being a branch of the eighth pair, it also stands intimately related to the spinal accessory, which receives filaments from the lateral tract as far down as the sixth cervical, while its connection with the vagus renders the circuit complete and gives ground for the peculiar pathological phenomena referred to.

In support of the theory of neurotic influence in the causation of amygdalitis, it may be observed that the lymphatics of the submaxillary base, as well as the buccal and salivary glands, are always more or less involved. That sensation popularly known as "creeping of the flesh," supervening upon certain conditions of mental horror, and the quivering of the subcutaneous areolar tissue in bodies recently dead exemplify this peculiar nervous condition, which is somewhat difficult to describe. The irritation of the spinal accessory within the cranium induces convulsive movements in such muscles of the larynx as are supplied by branches of the vagus, showing its accessory relationship to that nerve, as also the mixed quality of its filaments, while the glosso-pharyngeal, being a nerve of common sensation, acts centripetally to reflect stimuli to adjacent contractile surfaces, chief among which are the pharyngeal constrictors, tonsils, and fauces, as well as the tongue itself as far forward as the foramen cæcum (Gray), all of which are intimately involved in acute forms of the disease.

It was a matter of early observation, recorded by Luys, Neftel, and others, that severe mental as well as physical impressions were potent in inaugurating pathological processes in such structures as hereditary or fortuitous circumstances had sufficiently debilitated, and it is now admitted by all neurologists that when the mind is intensely occupied, very slight neurotic stimuli will produce involuntary and reflex movements of corresponding intensity. Mr. Darwin records it as a fact of his observation that an instinctive reflex act may override even the strongest efforts of volition, and Mr. Kirke assumes, as the result of experiment upon frogs, that both optic lobes and optic thalami are distinctly concerned in the government of these reflexes, although it is the opinion of most physiologists, Mr. Foster among the number, that, as reflex acts are performed after division of every segment of the cord, the reflecting power of the latter is almost, if not wholly, distinct from that of the encephalon.

As the existence and locality of the ano-spinal and vesico-spinal centers have long ago been demonstrated, it is not improbable that adeno-spinal centers also exist, any strong mental emotion acting upon which might readily affect the circulus tonsillaris, as it is well known to affect the vesical sphincters, and produce amygdalitis without *any* exposure. Indeed, both Virchow and Carswell, as well as the late Professor Vanzetti, of the University of Padua, in treating of lymphangeiectasis, definitively teach that the lesion may be produced by any cause, either *mental* or *physical*, affecting the general health, and Professor Willard Parker as long ago as 1856, speaking of concussion of the nerves, makes significant statements bearing in the same direction.

In relation to the selective seats of morbid action resulting from neurotic impressions, it must be apparent that impulses affecting the spinal structures must of necessity be of spinal origin, since the tonicity of all muscles is only destroyed by section of the cord. While we have in the ordinary muscles of contraction the tabular membrane blending with the sarcolemma and the motorial end plates intimately interwoven with the substance of the fiber, we find in the structures under consideration the sensitive end bulbs of Krause, any irritation of which may, of course, produce tonsillitis; but that it *may* supervene even without this irritation I am radically convinced.

What, then, is our morbid anatomy and *rationale* of treatment? First we should have sudden occlusion of the follicles induced by a mental impulse, transmitted to the motor nerves with consequent retention, and at the same time stimulation of secretion, which accounts, in my opinion, for the sudden onset of quinsy; followed by rapid inflammatory action, tumefaction, and suppuration of the tonsils, the glands of the mouth generally sympathizing and discharging excessive quantities of thick, ropy, and tenacious mucus.

Now, as to treatment, the first indication prior, of course, to the suppurative stage, would be a powerful solvent of animal membrane, such as papaine, which Wurtz and Bouchut pronounce the most rapid solvent of albuminous substances (Bartholow, Chapman, Potter), bicarbonate of sodium, or lactic acid by spray. Systemically, agents which depress the motorial function of the spinal cord—aconite, veratrum, and pulsatilla. The use of belladonna I have not been fortunate in, notwithstanding the apotheosis accorded it by the *savants* of the homœopathic school, and many regular practitioners besides. It dries the mucous membrane, and consequently antagonizes the action of the remedies already spoken of. Granted that it momentarily paralyzes the function of secretion, yet the testimony of Brunton, Wood, Gundry, and many others clearly shows that an enormously augmented secretion quickly follows.

I have found, acting upon my own theory in the matter, almost uniform success in a gentle but sustained opium narcosis, fortified, to prevent nausea and depression, with spirit of ether or one of the bromides, and accompanied, as spoken of, by the solvent spray.

If the barest chance of abortion exists, the course laid down will, I am convinced, afford the best hope of success, while after the inauguration of the suppurative stage the case becomes one for the nurse rather than the physician, if the knife be not called into use.

The astringent lotions or gargles so commonly used, while highly beneficial in staphylitis, pharyngitis, and other purely membranous inflammations of the mouth and throat, will be found worse than useless in this affection, although antiphlogistics are indicated in all.

IMPACTED URETHRAL CALCULUS IN A BOY OF THREE YEARS.*

By F. M. CRANDALL, M. D.

The patient, a boy aged three years, was brought to the dispensary February 5th. Three days before he had been seized with fever and vomiting, accompanied by soreness of the mouth. Examination revealed an ordinary follicular stomatitis, to which the symptoms were evidently due. Castor-oil had been given on the first day. It acted normally, but had been followed by persistent bearing-down pains and tenesmus. The rectum had been forced down almost into a condition of prolapse. But little urine had been passed since the onset of the disease, seventy-two hours before. Free doses of sweet spirits of niter had not increased the amount.

Examination showed a hard mass lying in the urethra about one fourth of an inch from the meatus. The glans was somewhat swollen, the meatus reddened, and the rectum was in a state of partial prolapse. The mass was reached with dressing forceps, and after some difficulty, due to slipping of the forceps and scaling off of the outer portions, it was removed. There was some laceration and bleeding, but it was not serious and gave no after-trouble. The child at once passed a large quantity of normal urine, and from a condition of restlessness, moaning, and crying, lay quietly back in the mother's lap and was soon asleep.

Two weeks before there had been a similar but milder attack, lasting two days. The child was fretful, passed urine in drops, and had the same straining at the rectum. During the previous months there had been occasional attacks of screaming and crying, for which no cause had been discovered. Retention of urine had not been noticed. Otherwise the child had been exceptionally healthy and had never had any severe illness. He had never passed milky urine, nor had any sediment been noticed. There had been no enuresis.

The mother is healthy and has had ten children—all living and healthy. The father has had two attacks of acute articular rheumatism—one last winter and one sixteen years ago. No history of rheumatism or growing pains could be obtained among any of the children.

The child was perfectly free from symptoms until March 3d, when he contracted diphtheria, from which he died. The mother failed to visit the surgeon to whom she had been directed for examination. It is impossible to say, therefore, whether there were other stones in the bladder. The urine examined one week after the removal of the stone was normal. The calculus weighed four grains and three quarters and consists of a uric-acid nucleus with a phosphatic crust. It was five lines in length, the transverse diameters being four lines and two lines and a half, respectively.

Though the onset of the stomatitis and symptoms due to the stone were thought to be simultaneous, there would seem to be no further connection than that of coincidence. The symptom of chief interest was the marked forcing down of the rectum, which to the mother's mind was the chief trouble. This was not continuous, however, as in the cases recently reported by Dr. Caille and Dr. Fruitnight, but only during the period of impaction in the urethra.

Aside from these two attacks and possibly what the mother called the "screaming spells," no symptom could be discovered which could in any way be referred to a calculus.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, JULY 26, 1890.

THE JOHNS HOPKINS HOSPITAL.

It would not be easy to overrate the importance of this institution, which was opened in Baltimore a little more than a year ago. Much has been published about it, referring chiefly to its prospective features, and that has made a decided impression on members of the medical profession and on philanthropists in general; but a record of what has been done is likely to make a still deeper impression. This seems to have been the trustees' conviction, and accordingly they asked Dr. John S. Billings, whose efficient aid in planning the institution they cordially acknowledge, to prepare a description of the grounds and buildings. This he has done, and his description, together with certain introductory matter, including his own address at the opening of the hospital, makes a quarto volume of more than a hundred pages of letter-press, followed by fifty-six full-page plates. Most of the plates are architectural plans and sections, but many of them show views of the buildings, including a number of interiors. The views are excellent reproductions of well-made photographs. They are very artistic pictures, but it is apparent that in their preparation there has been no straining after striking effects. The letter-press of the volume is correspondingly creditable as a piece of mechanical work.

From a study of the description and the illustrations it is abundantly evident that in the hospital, as in the volume, the adaptation of means to ends has been held paramount to mere pleasantness of aspect. The buildings are plain, but well proportioned, conveniently distributed over the grounds, and of an attractive general appearance. The same may be said of such of the appliances as are described and figured. In all this Dr. Billings's guidance has been apparent from the outset, and the handsome way in which this is acknowledged by the trustees is most gratifying, for it is seldom that a medical man's work is so appreciated.

It may be remembered that, when the trustees began their task of carrying out Hopkins's instruction to provide for a hospital that should, "in structure and arrangement, compare favorably with any other institution of like character in this country or in Europe," they first, also in accordance with his injunction, sought advice. They procured plans and descriptions of what such a hospital ought to be from a number of men familiar with the workings of great general hospitals. Each of these men wrote an essay, and the essays were studied by the trustees and published in the form of a volume. The trustees thus incurred a debt which they now repay by the publication of the volume before us—one that will go far to

assist the designers of hospitals yet to come in doing their work satisfactorily and without undue loss of time.

THE MIDWIFERY DISPENSARY.

The task of teaching obstetrics practically to medical students is one that, for its full and satisfactory accomplishment, calls for agencies and appliances that can not be put into operation without much good management on the part of the teachers, to say nothing of their self-sacrificing devotion to the work. To make the student a mere spectator in a lying-in hospital is not enough; being relieved of all responsibility, he is apt not to draw upon his own capability to the extent necessary to train it for the demands that he will eventually have to make on it in his practice. He who would study the art of obstetrics to the greatest advantage must exchange the comparative ease of hospital life for hard work in the tenement-houses. Lying-in hospitals are very useful institutions undoubtedly, serving as a refuge for the homeless and the deserted; but their maintenance is expensive and the number of their inmates is necessarily limited. In any degree to which it is practicable to multiply them, they can not afford all the aid, or even a tithe of it, that the community wishes to furnish to poor women in their time of need; hence it is most desirable that their work should be supplemented to the utmost by organized medical attendance on poor women in their own homes.

Organizations for that purpose have been at work successfully in New York for many years, but they have never been adequate to the amount of work to be done, and in some respects they have been defective in what might reasonably have been expected of them. We are very glad therefore to be able to announce the recent establishment of an obstetrical institution which, after close observation of its methods, we look upon as not only an important addition to our agencies for ameliorating the condition of the poor, but also as an educational resource of the most promising kind. This is the Midwifery Dispensary, which has been in operation since last December. It is situated in a dense tenement-house district, at No. 312 Broome Street, a short distance east of the Bowery. No medical treatment is carried out in the house; the premises occupied by the dispensary consist only of offices in which sufficiently minute and very carefully arranged records are kept, of sleeping-rooms for the resident physician and the students, and of store-rooms. There are three attending physicians, all of whom are men of experience in obstetrics and have been engaged in teaching it for a number of years. One of the physicians is in attendance at the house daily for a certain number of hours, and is always, when it is practicable, present at a confinement. The material appliances in the way of instruments, dressings, medicaments, etc., are ample, and the establishment is perfectly in readiness to afford its full resources at short notice and to meet any sort of obstetrical or puerperal complication.

Most praiseworthy discretion has been shown in settling the extent to which students are allowed to take part in the observation and conduct of cases. The details of the plan are too many to be mentioned in this article; it is enough if we say that they allow the student the fullest scope compatible with safety, and that they secure to the patient the presence of a licensed physician invariably. In return for a very small fee a student resides in the house for a specified term, and takes part in the management of a definite number of cases. Students are allowed to renew their terms of residence when it can be done without excluding other applicants, so that a continuous residence of considerable duration is often practicable. They are provided with the means of pursuing their studies, and their personal comfort is well looked after.

Many an established physician, looking back upon the disadvantages under which he slowly and laboriously and timidly acquired his knowledge of obstetrics, will be glad to learn of the facility with which a practical familiarity with the art may now be gained; if he will also commend this and kindred institutions to his benevolent friends and patients, he will aid materially in furthering the work of medical education as well as in promoting the alleviation of distress. In advancing both these purposes the medical profession has always been earnest and active.

MINOR PARAGRAPHS.

OXYGEN INHALATIONS IN PNEUMONIA.

The *Lancet* remarks that the action of oxygen inhalation is very often disappointing. It seems in practice far more inert than one might reasonably expect from its life-supporting properties. Various explanations have from time to time been offered, but its efficiency still remains rather circumscribed. One of the diseased conditions in which its inhalation has been most beneficial is the dyspnœa of nræmic intoxication. Another disease has lately been pointed out anew by Dr. John Chambers as suitable for oxygen inhalation. This is pneumonia, and the time for using oxygen with benefit has been found by him to be that very critical stage when lividity and cyanosis testify to the difficulty with which the circulation is being carried on. Since the direct result of an impeded circulation is a deficient aeration of the blood, it is not surprising that oxygen inhalation affords a certain promise of relief. Under its use the lips recover their redness, the breathing becomes easier, and the enfeebled heart's action is re-enforced. Dr. Chambers is satisfied that he has saved life in cases in which, from all the indications present, a fatal result was inevitable.

EXHIBITIONISM; A SEXUAL PERVERSION.

M. Magnan has recently presented to the Société de médecine légale the history of two cases showing that variety of sexual perversion not infrequently observed among men living in cities, known as "exhibitionists," or those having the propensity to expose their genitals in public places or to individuals, usually women whom they meet in unfrequented places. According to the report of these cases in *Progrès médical*, one of the subjects presented unmistakable hereditary defect, and both showed present typical degeneracy. The author classes these persons with the kleptomaniacs, the pyromaniacs, and the suicidal and homicidal insane. These degenerate beings are ordinarily a great trial to the police and are exceedingly shrewd in the avoidance of arrest; but imprisonment has little deterrent or reformatory influence upon them. They are seldom persons

who have a steady form of employment. It is probable that they are psychically incapable of acquiring a regular trade or business or of applying themselves to its pursuit.

THE ROOSEVELT HOSPITAL.

Last year Mr. William J. Syms died after having bequeathed the sum of $350,000 to the hospital for the purpose of building an operating theatre. In expectation of receiving the legacy, the trustees set about excavating for the foundation of the building, but the validity of the will was contested, and they suspended the work. Now it is announced that the contest has been discontinued, and it is expected that the theatre will be built.

"INFANT INDUSTRIES."

A clerk in the employ of the Brooklyn Board of Health was recently detected in furnishing information regarding returns of births to certain selected manufacturers. The *World* remarks that he "is doubtless one of those kind-hearted persons who are in favor of protecting and helping along our infant industries."

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 22, 1890:

DISEASES.	Week ending July 15.		Week ending July 22.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	26	6	24	7
Scarlet fever	44	5	43	7
Cerebro-spinal meningitis	1	1	1	0
Measles	240	19	215	10
Diphtheria	54	15	72	21
Varicella	3	0	7	0

The Mississippi Valley Medical Association.—At the meeting to be held in Louisville on the 10th of October, Dr. John A. Wyeth, of New York, will deliver an address, and Dr. Frank Woodbury, of Philadelphia, will read a paper.

The Red Cross Society of Munich.—Mr. Henry Villard, of New York, is reported to have given the Red Cross Society of Munich the sum of $12,500 as a contribution toward the construction of a hospital for the society.

The American Chemical Society will hold a meeting at Newport, R. I., on Wednesday and Thursday, August 6th and 7th.

The Luzerne County (Pa.) Medical Society will hold a meeting at Glen Summit on Wednesday, August 6th, under the presidency of Dr. G. W. Guthrie, of Wilkesbarre.

The Medico-chirurgical College of Philadelphia.—Dr. W. C. Hollopeter has been elected Lecturer on Diseases of Children, and Dr. Ernest B. Sangree Director of the Histological Laboratory.

Change of Address.—Dr. Walter Lester Carr, to No. 8 East Fifty-eighth Street.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, for the week ending July 19, 1890:*

Arthur, William H., Captain and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for three months, to take effect September 15, 1890, or as soon thereafter as his services can be spared. Par. 1, S. O. 160, A. G. O., Washington, D. C., July 11, 1890.

Mays, Louis M., Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence on surgeon's certificate of disability granted in S. O. 4, January 6, 1890, from this office, is extended six months on account of sickness. Par. 16, S. O. 160, A. G. O., Washington, D. C., July 11, 1890.

Corbusier, William H., Captain and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for four months on surgeon's certificate of disability, with permission to leave the Division of the Missouri. Par. 4, S. O. 162, A. G. O., Washington, D. C., July 14, 1890.

Page, Charles, Colonel and Assistant Surgeon-General, Medical Director of the Department, is granted leave of absence for one month, to take effect the 30th instant. Par. 3, S. O. 91, Department of the Missouri, St. Louis, Mo., July 14, 1890.

Phillips, John L., Captain and Assistant Surgeon, is, by direction of the Secretary of War, granted leave of absence for two months. Par. 4, S. O. 164, Headquarters of the Army, A. G. O., Washington, D. C., July 16, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending July 19, 1890:*

Anzall, E. W., Assistant Surgeon. Detached from U. S. Steamer Galena and to wait orders.

Eckstein, A. C., Surgeon. Granted leave of absence for the month of August.

Penrose, T. N., Medical Inspector. Granted leave of absence for two weeks.

Cabell, A. G., Passed Assistant Surgeon. Granted leave of absence for the month of August.

Ashbridge, Richard, Passed Assistant Surgeon. Granted one month's sick leave.

Heyl, T. C., Surgeon. Granted leave of absence for the month of August.

Cooke, George H., Medical Inspector. Detached from Navy Yard, League Island, and ordered to the Pensacola.

White, C. H., Medical Inspector. Detached from the Pensacola and to proceed home and wait orders.

Hoehling, A. A., Medical Inspector. Detached from Naval Hospital, Washington, and ordered to League Island Navy Yard.

Wells, H. M., Medical Inspector. Detached from Museum of Hygiene and ordered to Naval Hospital, Washington, D. C.

Whitfield, James M., Assistant Surgeon. Ordered to U. S. Steamer Ajax and other Monitors.

Woolverton, Theoron, Medical Inspector. Ordered to the U. S. Steamer Philadelphia.

Lovering, P. A., Passed Assistant Surgeon. Detached from the U. S. Revenue Steamer Wabash and ordered to the U. S. Steamer Philadelphia.

Bailey, T. B., Assistant Surgeon. Detached from the U. S. Revenue Steamer St. Louis and ordered to the U. S. Steamer Philadelphia.

White, S. S., Passed Assistant Surgeon. Ordered to the Marine Rendezvous, San Francisco, Cal.

Society Meetings for the Coming Week:

Wednesday, *July 30th:* Gloucester, N. J., County Medical Society (quarterly); Middlesex, Mass., North District Medical Society (Lowell).

Letters to the Editor.

THE MANAGEMENT OF THE MENSTRUAL EPOCH.

4 King Street, New York, *June 26, 1890.*

To the Editor of the New York Medical Journal:

Sir: In your June 14th issue there occurs a letter entitled "The Management of the Menstrual Epoch," which refers to and recommends the use of tampons during menstruation, and claiming for such use, if adopted, the marking of "a new era in the alleviation of human suffering." The idea is a very old one among Eastern nations, and the use of paper-ball tampons (wood pulp and silk fiber) is universal among Japanese women.

I quote from Professor Wernich, late gynæcologist to the Medico-surgical Academy, Tokio, Japan,* as follows:

"The first rnle which a menstruating woman observes in Japan is *rest*. Absolute abstinence from sexual enjoyment is strict law; there are distinct prescriptions against locomotion in the honse, and especially in the street; cleanliness during that period, as washing is considered as very injurious, is taken care of in a quite peculiar way. To let menstrnal blood touch the body or the linen, which is to be still nsed, would pass for the *ne plus ultra* of uncleanness. Therefore the menstrnating woman kneads or rolls, with one of the sheets of white papers—of which she carries always a large provision, for that very pnrpose, in her right sleeve—a ball from the size of an almond to that of a large walnnt, and inserts it into the vagina, replacing it by another when it is soaked in blood. In cases of fluor albns I have also freqnently found snch paper balls in the vagina. From the number of the balls nsed in the menstrnation, conclnsions are drawn as to its abnndance and favorable course." ALBERT S. ASHMEAD, M. D.

Proceedings of Societies.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION IN SURGERY.

Meeting of Friday, February 21, 1890.

Mr. EDWARD HAMILTON in the Chair.

Erasion of the Knee Joint.—Mr. LENTAIGNE, at the request of the chairman, described the operation of erasion of the knee joint which he had performed upon a young man whom he exhibited. The patient had been two years and four months suffering from white swelling of the knee joint previous to the operation, bnt no external sinuses had appeared. The case seemed to be suitable for erasion, and he had performed the operation, which was his first of the kind, by making the nsual horseshoe incision. After dennding the patella he had sawed clear throngh the middle of it. Turning down the lower and turning up the upper fragments, respectively, he had removed all the synovial membrane, cleaning away a mass of tubercular tissne in the crncial ligaments. Then he had stitched with catgut the lateral ligaments, which were both cut, and the patella. The condition of the joint was that of pretty advanced tubercnlar disease. In parts, the synovial membrane was abont an inch thick, with a caseous mass in the center. Inside the joint there was apparently an abscess, dne to the breaking down of a caseous mass. As regarded after-treatment, he had applied permanent dressing, using plenty of iodoform and large rubber drainage-tubes, which remained for a month, when the knee was again dressed. The patient had worn Thomas's splint, which tended to the success attained. It was intended that he should retnrn after a year to get the knee flexed, bnt the speaker feared that in trying to restore full functional valne by forcible flexion harm might be done.

On a Series of One Hundred Cataract Extractions.—Mr. SWANZY read a paper on a series of one hundred cataract extractions. He employed the three-millimetre flap operation, with a very narrow iridectomy in the upper quadrant of the iris. He instilled eserine prior to the operation to facilitate the obtaining of a neat coloboma, which it was difficult to procure if the iris prolapsed, and the reduction, after delivery of the lens, of all the rest of the iris into the anterior chamber. Quite a narrow coloboma was required, and was sufficient to efficiently protect the eye against the danger of secondary iris prolapse in the course of the healing—a danger to which eyes operated on by the simple method were so liable, as it provided a gateway by which the aqueons humor contained in the posterior chamber might escape throngh the wound, without carrying with it a portion of iris. Mr. Swanzy considered that snch an iridectomy was no "mntilation of the iris," but rather a measure which rested upon a sound scientific basis, and which was calculated to protect the eye against a serious danger. In this series the iris was incarcerated in the cicatrix in one eye only. After the lens was extracted the wound was carefully searched with an iris forceps for any tag of capsnle which might have prolapsed into it, and if any was fonnd, it was drawn gently forward and snipped off with the scissors. A tag of capsule was fonnd in the wound in nine of the one hundred eyes operated on. He strongly recommended this proceeding. The antiseptic measures consisted in the washing of the patient's face with hot water and soap, and the washing and wiping out of the conjnnctival sac with a 1-to-5,000 solution of sublimate lotion jnst before the operation, while all throngh the latter the same lotion was used for wiping and irrigating the wound and snrface of the eyeball. No sponges were nsed, but small bits of lint which had been boiled in the sublimate solution, and which were kept stored in it. The solntions of eserine, cocaine, and atropine were all made with snblimate solution, 1 to 5,000. Prior to the operation the instruments were boiled, washed in absolnte alcohol, and laid ready for nse in a bath of a one-per-cent. solntion of carbolic acid. After the operation they were again washed in absolnte alcohol. The dressing consisted in a layer of lint previonsly boiled in sublimate lotion, and wet with it: over this absorbent wool similarly boiled and wet, then a layer of oiled-silk protective, and then the bandage. This was not disturbed for forty-eight hours. The results obtained consisted in ninety-three per cent. good vision, five per cent. moderate vision, and two per cent. losses. The two losses were due to suppuration, and were the only cases of suppuration which occurred. In each of them the operation had been normal.

The CHAIRMAN noted with interest the careful manner in which the antiseptic system of surgery was apparently carried out in the operations; and he suggested a discussion upon the value of iridectomy as part of, or an element in, the operation of cataract extraction.

Mr. STORY asked whether the series represented the last one hundred cases in which Mr. Swanzy performed the extraction of cataract by the three-millimetre flap, with iridectomy, and so inclnded cases complicated and uncomplicated—*i. e.*, with dislocation of the lens, synechia anterior, and synechia posterior, the result of old iritis. But even if the series consisted of one hnndred selected cases, the results attained were admirable, as showing a total loss of only two per cent., while achieving moderately fair sight in five per cent., and good in ninety-three per cent. (taking it as "good" when the patient had a vision of six sixtieths). In the *Dublin Medical Journal*, 1880, he himself had pnblished a series of his first forty-seven cataract extractions, showing a loss of seven or eight per cent., recording as loss or failure where the patient could not connt figures at a yard or two yards off, and he found that the records of eleven thousand or twelve thonsand extractions disclosed a similar percentage of failures. Hence the question which he asked. He agreed with Mr. Swanzy as to iridectomy forming part of the operation, being of opinion that it facilitated the removal of the lens and prevented the danger of prolapse of the iris. He also agreed

* *Geographico-medical Studies after the Experience of a Journey Around the World.* Chapter on Adult Men and Women of Japan. Berlin, 1878.

with Mr. Swanzy as to the importance of antiseptic precautions. In St. Mark's Hospital a different plan was followed. The eye was washed with a solution of hydronaphthol, and the instruments were boiled in the same, while the operation was done under cocaine. He did not, however, take the tronble Mr. Swanzy advocated, of inserting an iris forceps afterward to search for pieces of capsule. He dusted over the surface of the wound and eyeball with finely powdered iodoform. As regarded irrigation proposed by Dr. McKeown, of Belfast, for washing out the cortex, he had not found it useful. The cortex was injured by nearly all the substances employed to wash out the anterior chamber, even by pure water. In his paper he had advocated the three-millimetre flap extraction in opposition to the linear extraction of von Graefe, which was then in vogne. It was a mistake to call the operation von Graefe's, for the operation owed its existence to De Wecker, one of the great ophthalmologists of Paris. Shortly after De Wecker had described it he had read the paper, and had been struck with the simplicity of the operation, which he had been the first to perform in this country. He had advocated the operation, but it had met with Mr. Swanzy's disapproval at the time. Therefore it was a pleasure to find that Mr. Swanzy now considered it the best operation for cataract extraction.

Mr. Fitzgerald said that Mr. Swanzy had distinctly stated that, strictly speaking, the operation was not Graefe's, but was Graefe's modified. The operation which he himself had been in the habit of doing was identical with Mr. Swanzy's up to a short time ago, when he had determined to try the simple operation —the extraction without iridectomy. He did not make his incision quite the same as Mr. Swanzy's; he made his puncture a little outside the clear cornea, and he brought the upper part of the flap well into the clear cornea. For comparison he was anxious to give statistics—twenty-six cases of extraction without the iridectomy in hospital practice, and also fifty-six in private practice, and then going back and taking twenty-six with iridectomy in private practice; but the twenty-six hospital cases with iridectomy he had been unable to procure. He judged his results more hardly than Mr. Swanzy, who seemed content to take as "good" if he could procure the counting fingers at a few metres off. Up to the present he had himself no case to deplore, and he recollected no case of suppuration. Therefore, as far as he had gone, the results from the simple operation proved immensely superior to those obtained with iridectomy. The reasons which induced him to undertake the operation were those urged by De Wecker, and, so far, he had had no cause to regret it. Although he had had two cases of prolapse of the iris, he thought there was needless alarm, and that by using the eserine after the operation, by careful bandaging and keeping the patient quiet for twenty-four hours, there need be no apprehension of it. Of secondary operations he had had a good number, but not more than Mr. Swanzy. The difficulty of giving statistics of hospital cases arose from the fact that the hospital patients seldom returned unless compelled when they had got a cataract in the other eye; but in private practice the patients came to get further improvement of vision. As regarded antiseptic treatment, he carried it out more in the way Mr. Story described than in Mr. Swanzy's. He could not rise to the point of boiling the instruments, which was very destructive of them, at least of the handles. He used hydronaphthol, but he did not use atropine or eserine before the operation. In the dressings, bandage was the same as Mr. Swanzy's.

Mr. Maxwell would perform iridectomy where the cataract was large and hard, but would dispense with it where the cataract was soft and small. He would not select lenses till at least two weeks after the operation.

Mr. Swanzy replied. His one hundred cases were not selected, but related to all those in which he had operated to the end of 1888, excluding, of course, such a case as that of a man having a bad injury of the eye and among them a traumatic cataract, or of a young person with a cataract coming on. His classification of results was in accordance with the handy conventional method of recording them as adopted by Professor Knapp and others—viz.: "no improvement," 2; "moderate," 5; and "good," 93 per cent. But he would not set down as "good" the ability to count fingers merely at three or four metres. Where the vision reached the standard of six sixtieths he regarded that as good already, with every probability of getting better. With regard to antiseptics, he had found more satisfaction from the use of a 1-to-5,000 solution of sublimate than any other. He had no idea about hydronaphthol, but he abominated iodoform in every respect. As regarded the introduction of the three-millimetre flap operation into Dublin, he did not know of anybody having done it before himself. He had been performing it for some years, and whether or not Mr. Story began it two or three months before him did not matter. He did not call it von Graefe's operation. What he said was that it was known as von Graefe's operation, of which it was the lineal descendant; not as von Graefe left it when he died, but von Graefe's improved upon, and so properly called his. As to Mr. Fitzgerald's operation being or having been identical with his own, perhaps it was, so far as the position of the incision in the margin of the cornea went; but he was not quite sure that it was in respect of the minute coloboma or the particular care taken in respect of the capsule in the wound which he regarded as a vital matter. Prolapse of the iris with subsequent incarceration in the cicatrix was a danger, and in his series of one hundred cases it occurred once; but in Mr. Fitzgerald's fifty-two it occurred twice, being nearly four per cent. —a result nearly as good as Professor Knapp's. Mr. Fitzgerald's cases of full vision were due to his performing discission of the capsule, and not because he left out the iridectomy. As regarded iridectomy, its performance did not, as Mr. Maxwell had suggested, depend on whether the cataract was soft or hard, whether the patient was going to get a prolapse of the iris or not, but whether the wound would properly heal and remain healed by primary union and without rupture. He had yesterday received a letter from one of the most distinguished ophthalmic surgeons in the United States, who stated that in thirty per cent. of his cases he had had prolapse, sometimes coming on some days after the operation without apparent cause, and that when men recorded cases without prolapse he simply doubted their statistics. With regard to Mr. Maxwell's point of ordering lenses two weeks or so after the operation, they should not be ordered until the eyes were white, not watering.

SECTION IN MEDICINE.

Meeting of Friday, February 28, 1890.

The President, Dr. Atthill, in the Chair.

The Influenza Epidemic of 1889-'90, as observed in Dublin.—Dr. J. W. Moore read a paper, in which he considered the effect produced on the public health and on the bills of mortality in Dublin by the epidemic, and described his impressions as to the origin, nature, and course of the disease.

The lessons to be learned from the epidemic might be stated in the form of propositions, as follows:

1. Influenza was an acute specific infective disease of the miasmatic rather than the miasmatic-contagious class. Its virus or contagium, when once introduced into the body, acted primarily and quickly on the nervous system, producing the phenomena of an acute pyrexia, with singularly rapid pulse.

2. The disease appeared to be *pandemic* rather than *epi-*

demic, affecting multitudes at one and the same moment, both by sea and land—a known fact, which suggested to Dr. Hilton Fagge the view that the organisms which gave rise to influenza, if organisms there be, could not undergo multiplication and development anywhere except in the air itself. The virus of influenza was then a miasma, or what the physicians of the sixteenth and seventeenth centuries called a "fouling of the air."* In this connection, Hirsch, of Berlin, pointed out that influenza had not spread more quickly in our own times, with their multiplied and perfected ways and means of communication, than in former decades or centuries.† The prevalence of the disease was absolutely independent of season and weather—a fact which distinguished influenza from epidemic bronchial catarrh.‡

3. If this miasmatic or pandemic view of the origin of influenza was correct, there was no need to seek for a period of incubation, the virus being already "hatched" at the time of its reception into the human system—that was, at the time of infection. In several, if not in most, cases there was an interval between the reception of the poison and the development of the symptoms. The most common duration of this interval seemed to be one or two days. But this pseudo-incubation period might be explained on the supposition that in certain individuals an intact condition of the mucous membranes might present an obstacle to the entrance of the virus into the blood, and so delay the development of the disease.

Of course, it was not denied that the morbific agent or virus was capable of adhering to the human body, or to clothes, or luggage, or letters, so as to be conveyed from one place to another (Hilton Fagge). "But," adds that writer, "its subsequent growth and development is, doubtless, altogether independent of this kind of assistance."

4. Very young children seemed to enjoy a certain immunity from influenza, or to have the disease in a mild form.

5. Adults suffered severely in many cases, the symptoms being chills, headache, often sleeplessness, sometimes delirium, pains in the eyeballs, nape of the neck, small of the back, knees, and along the margins of the ribs; loss of the special senses of smell, taste, and sometimes hearing; smarting of the eyes, photophobia, lacrymation, otalgia, complete loss of appetite, bad taste in the mouth, nausea, and perhaps vomiting; constipation, but occasionally diarrhœa; cough, frequent sweating, loss of strength, fainting. Of course, it was only a selection from these symptoms that was present in a given case.

6. Influenza, while infrequently directly fatal, caused an indirect loss of life which was appalling, chiefly through complications affecting the respiratory and, in advanced life, the circulatory systems.

7. Influenza was a perilous complication of pulmonary consumption.

8. Other complications of which the author had had experience were epistaxis (one case), facial neuralgia (several cases), profuse sweatings (several cases), skin rashes (four cases—three were examples of papular sweat rashes, with sudamina; one was an erythema fugax), herpetic eruptions (several cases), cystitis, followed by mild orchitis (one case).

In contrast to dengue fever, the speaker believed that influenza was a non-eruptive fever. When rashes did appear they were accidental rather than essential or specific, and they resulted from hyperpyrexia, or profuse sweating, or from the ingestion of such drugs as quinine, or antipyrine, or salicylate of sodium.

9. Influenza seemed to have the property of picking out the weak point in an individual's constitution. If the patient was neurotic, nervous and neuralgic symptoms were likely. Any old tendency to catarrh of either the respiratory or the digestive mucous membranes was at once intensified in the presence or in the wake of this strange malady.

10. The febrile movement in even uncomplicated influenza was, as Wunderlich would say, "polytypical," or "atypical."

11. Influenza showed a marked tendency to relapse, and to this was largely due the indirect fatality of the malady.

12. The treatment of the affection turned upon common-sense principles. It was expectant, palliative, and symptomatic. There was no specific for influenza, but the most useful drugs to employ in its treatment were (1) quinine, (2) antipyrine (except in young children and the weakly), (3) salicylate of sodium, especially in effervescence, (4) phenacetine, and (5) effervescing citrate of caffeine.

Influenza, or Dengue, as observed at Kells.—Dr. Ringwood read a paper on dengue fever, which, he stated, had been endemic in the neighborhood of Kells for the last five years, the disease having appeared soon after the return of our troops from Egypt. The character of the disease for the first six months was that of bilious relapsing fever of so virulent a type that six of the cases observed by him were exactly similar to the cases of yellow fever which occurred in Dublin in 1826, and were then described by Dr. Stokes and Dr. Graves.

He held that the present form of influenza was a very mild form of dengue, generally free from eruption. The limits of his paper prevented his referring to treatment, except to say that he had found the best results were obtained by the free use of pure salicine.

The President suggested, as questions for discussion, whether the disease which had been described by Dr. J. W. Moore was a specific and contagious disease, or, as was held by some, merely an ordinary inflammatory cold, very common at the present time; and also whether the cases described by Dr. Ringwood were of the same disease which prevailed in Dublin or of an entirely different and specific disease.

Dr. Finny did not think that Dr. Ringwood had thoroughly proved his point as to the identity of the disease in Kells with that in Dublin. Having seen the lady referred to, in consultation with Dr. Ringwood, he had to acknowledge that he had never met with a similar case. The variations of the fever presented remarkable phenomena, the temperature in the same day running from 99° in two hours up to 105° F., which was reached between eleven and twelve o'clock noon, and in the evening it was down to normal. The lungs were largely affected with patches of pneumonic complication. It was noteworthy that the lap-dog suffered too, having a discharge from the nose, as showing that the influenza affected the lower animals.

Dr. McSwiney had met with cases characterized by frequent desire to urinate in large quantity, somewhat as in hysteria; also by fainting, epistaxis, pain in the frontal sinuses, followed by a discharge of pus; and, in the recovery stage, by diaphoresis.

Dr. A. W. Foot said the term "influenza," whatever it meant, had been dragged in by the neck and shoulders as a *deus ex machina* to explain, in the case of the first paper, diseases with the old-fashioned names of "feverish cold," "heavy cold," as distinguished from "light," "rheumatic cold," or other forms of ordinary catarrh; and, in the case of Dr. Ringwood's paper, anomalous forms of eruptive fever. He had entered the room with but slight respect for influenza; yet when he heard cholera and yellow fever mentioned in the same breath all that was requisite to make him a perfect convert to its importance was to give it a spice of hydrophobia. But then

* Hirsch, *Handbook of Geographical and Historical Pathology*, vol. i, p. 34, New Syd. Soc., 1883.

† *Op. cit.*, p. 36.

‡ Cf. Hirsch, *op. cit.*, p. 26.

there was the high death-rate from influenza recorded by the Registrar-General. Man, woman, and child, horse, dog, and cat had suffered, and the weary, over-worked dispensary doctor made the shortest diagnosis and put down "influenza." Hence the alarming statistics. He preferred to rely on observations in hospital practice rather than on those in private. Fagge was entirely against the miasmatic origin of influenza, using the word "miasmatic" as telluric. The prevalence of influenza in every climate, torrid and temperate, in every soil, dry and moist, in high elevations and lowlands, and in fleets on the ocean, showed that it had no miasmatic or telluric origin. As regarded treatment, he had not heard any recommendation of rum punch, which he had known to cure many cases.

Dr. C. J. Nixon said Dr. Foot's remarks implied a complete disbelief in the existence of influenza as an epidemic, especially occurring at the present time. He required proof where probability only was to be had. But there was one important fact that, according to the returns of the Registrar-General, in Paris the deaths for the last week of December, 1888, amounted to 955, while for the last week of last December the deaths were 2,374; and again, taking the first week of January, 1889, the deaths were 970, while in the first week of January of the present year the deaths were 2,683. There must surely be some very unusual conditions to produce such a striking increase in the death-rate.

Dr. J. Bellew Kelly (Drogheda) felt disappointed at not having heard more as regarded treatment. He had learned nothing that had not been on record for centuries, especially in connection with the epidemics of 1510 and 1743, whatever the name of the disease, whether *la grippe*, influenza, or dengue. Every form of disease of a febrile type was liable to all sorts of complications. He had had three hundred cases, and in all these he had not treated one pregnant woman.

Dr. J. W. Moore, in reply, said Dr. Foot had not correctly stated Dr. Hilton Fagge's view, which was that the organisms of influenza could not undergo multiplication and development anywhere except in the air itself; and that constituted the distinct theory of miasma; while Hirsch considered the virus of influenza was a miasma or fouling of the air. If influenza was not an epidemic, Dr. Foot had given no explanation of the excessive death-rate of January, 1890, which was certainly not due to the weather. The death-rate was opposed to all accepted theories of the influence of the weather. Indeed, in spite of the mild weather, the death-rate exceeded that which was incidental to the intense cold of January, 1881. His classification was nearly the same as Dr. Nixon's. He gave five classes—cardiac, pulmonary, gastric, febrile, rheumatoid, yet all of a febrile type. Dengue and influenza were absolutely and positively distinct. There was not a single case of dengue in Dublin or, he believed, elsewhere in Ireland. It was an accepted doctrine that dengue was a tropical or subtropical disease. No true case of yellow fever could possibly occur in Ireland, for under 70° F. was fatal to the disease. His theory of pseudo-incubation was, that the virus of the disease seemed to be hatched and multiplied in the open air, and then lodged on the persons of individuals, who acted as fomites of the disease. There was no evidence to show that the virus was multiplied and developed within the system.

NEW YORK CLINICAL SOCIETY.

Meeting of May 23, 1890.

The President, Dr. L. B. Bangs, in the Chair.

The Dosage and Administration of Creasote in Phthisis.—A paper on this subject was read by Dr. W. H. Flint. (See page 85.)

Dr. Beverley Robinson said that he was much gratified at the very complimentary manner in which Dr. Flint had referred to his paper on creasote as a remedy in phthisis pulmonalis. He was particularly glad to take part in this discussion, as he believed in creasote as a very useful remedy in this disease. Prior to using it in an accurate and extensive way, he had tried all the vaunted methods in treating phthisis. For some time lavage and gavage had inspired him with much confidence, and he had hoped that we might thus so improve the nutrition of phthisical patients that the *Bacillus tuberculosis* would ultimately be compelled to relinquish its hold. Certainly, patients often did gain considerably in weight, but the physical signs in the lungs remained stationary. He had also believed, during quite a period of time, in the marked beneficial effects resulting from intrapulmonary injections of different kinds. He had now practically abandoned them, as he had lost faith in them, except in a very limited number of cases. After reading Bouchard's paper when it was first published, he had commenced using creasote; but in the beginning he had only had faith in it as a good anticatarrhal agent, to be ranked in the same category with many similar drugs that were said to have a special effect in lessening bronchial inflammation.

Later on, and very soon after the first publications in regard to the useful effect of the drug appeared in Germany, he had taken up his observations on creasote with considerably more accuracy and attention to the smallest changes in signs and symptoms brought on by its use. The result had been to convince him of its great utility. Prior to using it he had become very skeptical as to the curative influence of drugs in this disease, and he had given cod-liver oil and the hypophosphites—particularly to hospital and dispensary patients—with great incredulity as to their beneficial effects. Now and for some time past his faith had returned in a measure. In his experience, creasote must be given in small doses and continued a long time if we wished to obtain really good effects from its use. It was possible that some patients might bear large doses well, but it was always a risk to insist upon them. He had always used creasote by the mouth or in inhalation, and had had no experience with the method of giving it by the rectum. He was not favorably disposed toward this other way of giving the drug. Creasote should be pure, well diluted, and perfectly dissolved, in order to prevent any possible danger of stomachal intolerance. The dose of a half to a minim should be given five or six times in twenty-four hours, and increased in amount very slowly. It should be continued for months at a time, and indeed so long as there was any indication for its use. Taken in this way, it would usually produce good, and at times remarkably good, effects. Sputa would diminish and disappear, nutrition was benefited, strength increased, and cough arrested. The local signs were sometimes much improved. He had known, in at least two cases, the bacilli to disappear entirely from the sputa, where they had previously been recognized. In several cases he believed he had seen his patients recover. Now, he could not say this of any hospital or dispensary patients thus affected whom he had formerly treated with cod-liver oil and the hypophosphites. Altogether, in his judgment, creasote was the best remedy we now were in possession of for the amelioration and possible cure of pulmonary phthisis. We must not, however, run risks of disgusting our patients with it by increasing the doses too rapidly. Above everything, we must preserve the digestive organs intact, and must not interfere with the assimilative process. If we did this, we lost immediately all the possible good effects from creasote, and took away from the patient one of his reliable chances of living. Whenever it could be carried out, he liked the combined method best—of inhalation and administration by the stomach. In this manner

he was sure we should obtain our most welcome results. He would be glad if these expressed opinions should carry conviction, and make it almost obligatory for any one treating a case of phthisis to give creasote.

Dr. W. H. Katzenbach remarked that, for the last year or so, he had employed creasote in the treatment of phthisis in private practice, with results corresponding with those mentioned by Dr. Flint and Dr. Robinson. Under its administration, in a good proportion of cases, appetite and digestion had improved, cough and expectoration had subsided, fever abated, nutrition increased, and the patient gained in weight. A recent case would illustrate this. A young woman, aged twenty-three years, had consulted him early in March of the present year with signs of phthisis in the second stage, involving a considerable portion of the upper lobe of the right lung anteriorly. The physical signs were dullness, broncho-vesicular respiration, increased vocal resonance, and subcrepitant râles. Her temperature was 100·5° F., pulse 120, and respiration 32. Weight, one hundred and seven pounds. She was given creasote in conjunction with cod-liver oil and extract of malt. By the middle of March her appetite had improved and her cough had diminished. Menstruation, which had been suppressed, reappeared, and she felt stronger in every respect. By the latter part of April her temperature was 98·5° F., pulse 80, and respiration 24. The respiration over the affected lung was still broncho-vesicular, but the râles had disappeared. Her weight was one hundred and eleven pounds and five eighths.

In medicinal doses, Headland had said that creasote had "a double action, being anodyne, like hydrocyanic acid, and a mucous stimulant, like turpentine" (quoted by Stillé).

When its use was begun, creasote might increase cough and expectoration from its liquefying action on the sputa, but subsequently the secretion diminished or was arrested, and cough was relieved. In the late stages of phthisis, with cavities, high fever, copious expectoration, loss of appetite, and impaired digestion, the results had not been favorable. The following formula was the one commonly used:

℞ Creasoti (beechwood)..... ..... ʒj;
Glycerin..... ad ℥iij.

M. Sig.: Take half a teaspoonful after meals and at bedtime, with whisky, a half to a tablespoonful, and water two ounces.

Dr. W. G. Thompson said that it had been his fortune to succeed Dr. Flint several times in his hospital service, and he wished to add his testimony to the value of the results of the creasote treatment in many of Dr. Flint's cases of phthisis. He had used the drug extensively for a number of years, and was convinced that it was, upon the whole, the most useful remedy that we possessed for controlling many of the more urgent symptoms of phthisis, notably diminishing cough, expectoration, and dyspnœa, and favoring gain in nutrition. In cases fairly advanced, he believed in pushing the administration of the drug to the limit of toleration. This limit was considerably extended by taking great pains to secure a pure wood creasote, and to administer it in the careful manner described by Dr. Flint. The drug was of special value in that it might be given in several ways—by the mouth, by inhalation, or by the rectum. When the stomach showed signs of irritation from large doses of creasote, he had found it to be still very well borne when administered by the rectum in five-minim doses, in emulsion, or by inhalation. If the inhalers worn were not deep enough, excoriation might result, and he mentioned three cases in which he had seen severe ulceration of the nose and chin from the careless use of inhalers with creasote. Notwithstanding the results of experiments upon animals, alluded to by Dr. Flint, the speaker thought that we were still completely in doubt as to the mode of action of the drug in phthisis. In man there were some fourteen pounds of blood, in which any so-called "antiseptic" remedy must inevitably be diluted when absorbed, and it was easier for him to believe that creasote might act by altering in some manner the tissues or "soil" in which the tubercle bacilli grew, or by improving bodily nutrition, than to admit that its influence was in any way germicidal, even when inhaled. In the latter case it was difficult to prove how deeply it diffused into the lungs, or that it ever came in direct contact with many foci of bacilli.

Reports on the Progress of Medicine.

GYNÆCOLOGY.

By ANDREW F. CURRIER, M. D.

Contribution to the Subject of Fibromata of the Uterus (Walton, *Arch. de tocol.*, December, 1889).—The object of this paper is principally to indicate the line of conduct which is proper for the general practitioner in meeting the ordinary difficulties which are associated with uterine fibromata. Radical treatment is not believed in for such conditions so long as conservative treatment is suitable. The following propositions are submitted:

1. With fibromata which completely fill the uterine cavity, rapid dilatation will enable one to make a diagnosis, and facilitate an operation if the latter is indicated.

2. Ablation of the neoplasm will check the hæmorrhage, even though a second growth is developing in the uterine wall.

3. Forced dilatation may, of itself, rupture the capsule of a submucous fibro-myoma, the spontaneous enucleation of which may follow.

4. Forced dilatation combined with curetting will always arrest hæmorrhage from fibromata which are not attackable *per vaginam*.

5. Forced dilatation by facilitating the return circulation may lead to involution, to diminution, and to clinical disappearance of the tumor.

6. The suppression of hæmorrhage and of compression symptoms, the absence of pain and of all disturbance, constitute a cure clinically.

7. The best means for overcoming the fœtid condition of the leucorrhœal discharge attending these tumors, and so of avoiding autoinfection, is to dilate freely the uterine cavity and disinfect it.

Concerning Gastric Affections in Connection with Diseases of the Female Genital Organs (Rosenthal, *Ctrlbl. f. Gyn.*, Nov. 30, 1889).—The author disagrees with Hegar, Engelhardt, and others who look upon the nervous disorders connected with gastric affections as spinal-cord symptoms, and seeks to find their explanation in an irritation of certain roots and plexuses, including the ischiadic and crural and also the root areas of the cauda equina. Neuritis of the nerve-roots with severe symptoms is a rare occurrence. Those forms of digestive disorder which have a reflex relation with disease of the uterus and its annexa usually appear as dyspepsia, cardialgia, and vomiting. Two different types of digestive disorder may be distinguished. In that form which is characterized by cardialgia, vomiting, and pneumatosis, there is superacidity as the result of the gastric irritation; in the other form there is insufficiency of hydrochloric acid, indicating gastric exhaustion. In the first form the condition of the urine is of especial importance. To be rational in one's treatment of these cases they should be carefully distinguished from those in which there is a deficiency of acid. In the first the author prescribes Carlsbad water, borax, or a mixture of carbonate of potassium and bismuth; also large doses of bromide of potassium morning and evening, and in some cases hydrotherapy. In the second form large doses of hydrochloric acid are indicated, perhaps with the addition of pepsin.

The Electrical Treatment of Uterine Fibromata (Apostoli, *Concours*, Nov. 9, 1889).—The electrical treatment of fibroid tumors of the uterus which was devised by Apostoli in 1882 was recently discussed before the Paris Society of Surgery in connection with a method which

purports to have superiority over all others in that it is new, and that it rests upon the use of currents of moderate intensity, upon intra-uterine action, and upon frequent changes of the current.

Apostoli opposes these pretensions as follows:

1. This method, devised by Championnière and Danion, is not new, and is only the reproduction of old methods which have been tried and, in part, abandoned.

Apostoli claims priority and originality in the use of all medical electric currents exceeding fifty milliampères. For two years he used no current exceeding seventy milliampères, but subsequently he found it safe and advisable to use stronger ones, the intensity being moderated according to the uterine or circumuterine intolerance, and increased in complicated forms of endometritis or in severe hæmorrhage.

Aimé Martin and Chéron discovered in 1879 the extra-uterine action of the current, and defined its action upon the cervix and the vagina; they were also the first to use interruptions and reversions of the galvanic current. Benedikt also used reversions of the current prior to Championnière and Danion.

2. This method is inferior to that of Apostoli, because its authors still continue as surgeons to substitute for it, in certain cases, castration and hysterectomy; because they use it upon old or slightly sick women, and operate upon the younger ones; because the method is only vaginal and extra-uterine, thus omitting to cure a concomitant endometritis; because recurrences constantly occur unless they continue to use the treatment; because they do not profess that peripheral inflammatory exudates disappear; because their use of sodium-chloride solutions shows that they do not regard their method as reliable; because they have not demonstrated anatomical reductions in the tumors treated.

The experience of Championnière and Danion rests upon seven months' trial in eleven cases, while Apostoli has tried his seven years, many thousands of cases having been treated.

Apostoli asserts that his method is inoffensive and supportable if one confines himself to the rules which he (Apostoli) has prescribed. His method is the most efficient:

1. Because it is a sufficient method, and in most cases can supplant surgery in the treatment of fibromata.

2. Because it does not select its cases, and benefits young and old.

3. Because it makes use of ,vaginal galvano-puneture, either by itself or in connection with the intra-uterine action which relieves lesions of the endometrium.

4. Because failure with it is exceptional with simple fibroid tumors—that is, with those which are not fibro-cystic, which are not complicated with ascites, and which have no peripheral lesions of the annexa.

5. Because with this method recurrence is exceptional, most of the results being permanent after treatment has been sufficiently prolonged.

6. Because it includes in its sphere of action under formulæ of different intensity and localization the treatment of fibromata, endometritis, metritis, and many cases of oophoro-salpingitis.

7. Because it can dispense with the use of all additional methods of treatment.

8. Because it produces anatomical reduction of the tumor to a greater or less extent.

At a meeting of the Paris Surgical Society (*Concours*, Mar. 15, 1890), Lucas-Championnière spoke concerning the electrical treatment of fibroid tumors. He uses a method to which Apostoli's name is attached, but in a different manner from Apostoli, inasmuch as he penetrates neither the uterine tissue nor the uterine cavity with the electrode. An electrical tampon is placed against the vaginal portion of the cervix, and the current is reversed from time to time. The intensity of the current used does not exceed 80 to 120 milliampères. In all cases this treatment has been well tolerated, and causes a disappearance of the feeling of heaviness, the hæmorrhage, and the pain; it also causes diminution in the volume of the tumor. Such results have often been seen in women forty to forty-five years old, but in some cases the disease has been very rebellious to treatment.

Le Dentu called attention to a rare form of fibroma in the abdominal wall of a woman upon whom he performed ovariotomy in 1888. The following year an enlargement appeared at the site of the cicatrix, and this proved to be a tumor as large as a good-sized nut which was adherent to the deeper portions of the skin and abdominal wall. It was easily removed, and the author thinks it was not a keloid growth but a neoplasm of a fibrous character which started from the cicatricial tissue.

Alexander's Operation.—At the same meeting (*ibid.*) Lagrange called attention to a patient upon whom he had performed Alexander's operation for backward displacement of the uterus. The operation was done in May, 1889, and had resulted in the disappearance of the symptoms which were present prior to the operation. No pessary had been used since the performance of the operation, and the uterus remained in good position.

Terrillon said that the fixation of the ligaments to the pillars of the inguinal ring was sometimes inconstant, and that it was better to use a pessary for several months after the performance of the operation.

Trélat thought that one could say within a month after the performance of Alexander's operation whether the success would be permanent or not. Failure is sometimes due to rupture of the thin and tense fibers of the shortened ligament. In performing the operation, he thinks that sections 10 or 12 centimetres long should be removed from each ligament.

Bouilly believed that success or failure in Alexander's operation depended largely upon the condition of the pelvic floor, which under certain circumstances played a very important *rôle* in the reproduction of retroflexion. In some women one can succeed in maintaining the uterus in its proper position after Alexander's operation only by supplementing that operation by the performance of perinæorrhaphy or colporrhaphy.

Electrotherapy in Slavjansky's Clinic (Massen, *An. de Obst., Ginecop. y Ped.*, February, 1890).—The battery which was used by the author was one of Gaiffe's with thirty-six cells, the latter being the modified Leclanché containing a solution of peroxide of manganese and chloride of zinc. He also used a smaller battery containing twenty-four cells containing the bisulphate-of-mercury solution. All antiseptic precautions were used in administering the treatment, not only the instruments being disinfected, but also the genitals of the patient. The uterine sound was introduced through a vaginal speculum, this being contrary to the custom of Apostoli. At the beginning of a course of treatment the current should not be passed for more than five or six minutes; subsequently it may be used eight or ten minutes. Ten minutes should be the maximum time for the treatment of interstitial fibro-myomata. The intensity of the current should not exceed 50 milliampères at first, and this may be gradually increased in subsequent séances to 120 milliampères for inflammatory conditions, and 250 or more for fibro-myomata. To measure the intensity of the current, Gaiffe's horizontal galvanometer is recommended, while the resistance should be regulated by a rheostat, 200 ohms being a suitable resistance with currents of moderate intensity, while with those currents of 250 milliampères or more the resistance should not exceed 7 ohms. Inflammatory products do not perceptibly increase the resistance, but with fibro-myomata the resistance is decidedly augmented. The author agrees with Apostoli in affirming the hæmostatic action of the positive pole. Ordinarily the treatment may be given once in five days, but with fibro-myomata which are not very sensitive it may be given more frequently. If the treatment is external the patient should rest for an hour after receiving it and then attend to her ordinary duties, but in the treatment of fibro-myomata it is better that she should rest for the remainder of the day. The passage of the current does not usually produce much pain, and anæsthesia is therefore unnecessary. There may be smarting upon the abdomen similar to that which is produced by a sinapism; there may also be a feeling of compression in the uterus, and at times a dragging sensation about the waist. The feeling may be more intense if there is a focus of recent inflammation. If the negative pole has been used, there may be contractile pains like those of parturition two or three hours after the séance is concluded. Usually there is no pain at night and the patients can sleep quietly. At the beginning of a course of treatment there may be a moderate leucorrhœal discharge mingled with blood. All other treatment should be suspended while electrotherapy is being used, except the use of vaginal douches. During a period of five months and a half the author treated twenty cases of fibro-myoma, twenty-two of metritis and endometritis, and seventy of disease of the uterine appendages and the broad ligaments. There were

also three cases of amenorrhœa and one of hystero-epilepsy. In thirty-four cases a cure was effected, in eight there was no change perceptible, and in three the patients became worse. The author has formulated his conclusions as follows:

1. Apostoli's method merits the attention and sympathy of gynæcologists.

2. It represents one of the bases of conservative gynæcology, and has an assured future.

3. It is still in its initial period, and, like all electrotherapy, rests upon experimentation.

4. In the treatment of fibroid tumors it relieves pain and hæmorrhage, and restores the normal function of the uterus. Subsequently the tumor becomes movable as the result of absorption of inflammatory matter, and finally there is reduction of the neoplasm.

5. It offers perfect results for hæmorrhagic endometritis, and is a successful rival to the operation of curetting the uterine mucous membrane.

6. Before castration is performed the electrical treatment should receive a trial.

Irrigation of the Peritonæum (Delbet, *Ann. de gyn.*, September, 1889).—The author has made experiments with the view of ascertaining whether irrigation is really a good way of cleansing the peritonæum, and whether it may not cause, in a reflex manner, cardiac or respiratory syncope. The liquid which is poured into the peritoneal cavity is diffused throughout it, and this is an advantage if one is operating for general peritonitis, or in cases in which the contents of a ruptured intestine or an abscess have been poured upon the peritonæum; but if the object is simply to remove pus which has leaked into Douglas's *cul-de-sac* from a tube which has been torn in the course of its removal, irrigation may force the pus into or upon parts which were not previously soiled. Hence the body of the patient should be elevated during the process of irrigation and the intestines retained *in situ* by means of sponges. In many cases it will be almost impossible to remove all matter from the peritoneal cavity which enters it, and it will usually suffice to remove the greater portion of it. Irrigation of the cavity with fluid at a temperature of 48° to 50° C. will usually have no influence upon the temperature and respiration. It is usually better to have the temperature at 38° or 39° C., which is about the temperature of the body. The hæmostatic action of fluids at very high temperatures is doubtful. The quantity of liquid absorbed during the first few minutes of irrigation is considerable. If a 7-to-1,000 solution of chloride of sodium is used, the effect is that of indirect transfusion. A prolonged operation or excessive loss of blood would be an indication for irrigation with such a solution, even if the peritonæum did not require cleansing. This facility of absorption may constitute a source of danger if the cavity contains pus or fæcal matter, for they may contain soluble poisons which might be absorbed to the disadvantage of the patient. Pus or fæcal matter should be removed as far as possible with sponges before beginning the irrigation. The peritonæum may be irrigated with toxic solutions without danger of intoxication if a preliminary irrigation of the weak saline solution be used for ten minutes, and the irrigation with the toxic fluid be followed by another irrigation with the saline solution to wash away the excess of the former. The following are the indications for antiseptic irrigation of the peritonæum:

1. The diffusion of septic matter in the cavity in the course of a laparotomy.

2. Penetration of pus or fæcal matter into the peritoneal cavity prior to an operation.

3. Septic peritonitis.

4. Possibly peritoneal tuberculosis.

Ligature of the Uterine Arteries (Gubaroff, *Prog. Gin.*, Aug. 10, 1889).—The author has tried upon the cadaver a new method for ligating the uterine arteries, and Sneguireff has successfully performed the same operation upon the living subject. It consists in the intraperitoneal ligation of the nutrient vessels of the uterus, the uterine, the utero-ovarian, and the artery of the round ligament, the anastomoses which these vessels make with their vaginal branches being preserved to prevent necrosis of the uterus. The operation consists in a cutaneous incision, the same as for the ligation of the common iliac or the external iliac, the tendinous portion of the transversalis abdominis muscle being avoided. The lower extremity of the incision should reach the external inguinal ring. After dividing the three muscular layers of the abdominal wall and the transverse aponeurosis, the peritoneal sac of the iliac fossa is reached, and then, following the internal border of the psoas major, the point of division of the common iliac artery. Then the tissues may be retracted with a Sims speculum and the iliac artery followed until one reaches the emergence of the uterine artery, in front of which the ureter may be seen passing. The utero-ovarian or spermatic artery may also be readily seen at the bottom of the cavity and ligated. The latter vessel is accompanied by its veins and should be separated from them before ligation. The artery of the round ligament may either be ligated alone or in conjunction with the structure which it nourishes. The latter vessel proceeds from the inferior epigastric, and, as it is not always easy to separate it from the round ligament, it may be preferable to ligate the inferior epigastric. The ligation of the nutrient arteries of the uterus is indicated—

1. In inoperable cases of cancer of the uterus with profuse metrorrhagia.

2. In intraligamentous tumors and subserous myomata, in which cases ligature of the uterine arteries should precede intraperitoneal operations.

3. In cases of metrorrhagia, independent of appreciable anatomical lesion, which have resisted the use of the ordinary hæmostatics.

New Operative Procedure for reaching the Organs of the Pelvis by way of the Perinæum (Zuckerkandl, *ibid.*, Aug. 10, 1889).—The author has devised a method of procedure which enables one with more ease than any other, it is claimed, to expose the pelvic organs—namely, the rectum, sigmoid flexure, uterus and annexa, prostate gland, vesiculæ seminales, and posterior wall of the bladder—through the soft parts which constitute the perinæum. The principle upon which this new procedure is based is the following: If in the perineal region a flap is cut with three sides (⊓), the horizontal portion of which is situated three centimetres anterior to the anus with the lateral incisions diverging toward the sacral region, and if, after separating the external sphincter, the recto-prostatic cellular tissue is penetrated, and then the recto-vesical tissue in the male or the recto-vaginal tissue in the female, the insertion of the levator ani muscle in the rectum is released, the anterior wall of the rectum will appear, and then the fold of peritonæum which lies at the bottom of the excavation. The rectum being drawn downward, the peritoneal fold may also be drawn down toward the skin. The latter being opened, one has ready access, in the female, to the uterus, the tubes, the ovaries, and the broad ligaments. The application of this procedure to the operations which are performed upon the uterus offers the following advantages: First of all, the uterus is more accessible by this procedure. By the division of the fibers of the levator ani, the rectum may be displaced and access to the uterus obtained which exceeds in facility for execution that which is obtained by way of the vagina. Both the uterus and its annexa are made readily accessible by this step. The broad ligaments with the uterine arteries are readily ligated, which is not always the case when one operates through the vagina. There need be no fear of ligating the ureters. The entire genital tract can be readily inspected, and one can proceed to a more radical extirpation of the internal genitals than by other methods. Asepsis of the entire operative field can also be more readily accomplished.

Results obtained by the Total Extirpation of the Uterus (Kaltenbach, *Jour. de méd.*, Jan. 12, 1890).—Kaltenbach reports fifty-seven cases in which he has removed the entire uterus, the indication being carcinoma in fifty-three, sarcoma in two, and prolapse in two. He finds that the operation is always indicated for carcinoma when it can be easily performed, and he hopes in suitable cases to obtain complete cure. Theoretically, partial extirpation may be excellent and sufficient, but practically it is rarely indicated. In one of his cases a partial extirpation was performed upon a woman who was seven months pregnant, a carcinomatous node as large as a nut being found upon the anterior lip of the cervix. A wedge-shaped excision was made and the pregnancy pursued its normal course. In general, the author thinks that all operations for cancer should be extended beyond the vaginal insertion, total extirpation being preferable apart from its offering greater chance of immunity from recurrence of the disease. Only two

of Kaltenbach's patients died from the operation, one being from uræmia after ligation of the left ureter and wounding of the bladder. In two cases it was subsequently necessary to perform kolpokleisis on account of vesico-vaginal fistula. In three of the cases the patients were more than sixty years of age. Great stress is laid upon the importance of suturing the peritonæum and disinfection with salicylic and boric acids. In twenty-five of the cases of carcinoma a year passed without recurrence of the disease. Recovery from the operation was rapid. If the disease recurred, the thermo-cautery and chloride of zinc were used. In no operation was there severe hæmorrhage. In one case a cancerous fistula of the bladder was cured.

Curetting for Endometritis (Bouilly, *Jour. de méd.*, March 9, 1890).—The author gives the results of seventy-five cases in which he has performed curetting since 1887. He refers particularly to simple cases—that is, those which are not complicated by the presence of polypi or myomata; but he also refers to cases in which there may be a certain amount of disease of the annexa. In all of these cases curetting had been preceded by other treatment. The principal indications for the operation were hæmorrhage, leucorrhœa, and pelvic or sacral pain before or during menstruation. Pain alone, however, is not to be considered a sufficient indication. In twelve cases the operation was done without an anæsthetic, but such a plan is not to be recommended, on account of the pain which accompanies it. The operation should be preceded by dilatation, and the author used laminaria tents for this purpose, using at first a small one for twenty-four hours, and then a large one for twenty-four hours longer. There is little pain attending such dilatation. Next, the vagina should be irrigated, the uterus drawn down, and the endometrium curetted. The curetting is followed by an injection of tincture of iodine, or of carbolized glycerin, if the metritis is muco-purulent in character, and by a chloride-of-zinc application if it is hæmorrhagic. For the first few subsequent days the vagina is closed with a tampon of antiseptic material. The immediate results of these operations were: No accidents; absolute freedom from bad conditions. In many cases the pelvic or abdominal pain disappeared at once. In many other cases the best results were not obtained at once. In sixty-nine of the author's cases the histories were followed up for some time, and these cases were classified as cures thirty-nine, improvement fifteen, failure fifteen. In hæmorrhagic metritis the cures were especially frequent, and included nineteen cases. There were twenty cases of muco-purulent endometritis which were cured, the annexa in three of the cases being rather painful prior to the operation. With such a complication, it was found that the abdominal pain disappeared very slowly. The author has concluded that, if tubal disease really exists, no benefit need be expected from curetting. The cases which were tabulated as improved included those in which one or several of the symptoms disappeared. Of the fifteen unsuccessful cases, four were cases of hæmorrhagic and eleven of muco-purulent metritis. Curetting is indicated in chronic simple endometritis, and in the hæmorrhagic form it is a most valuable resource. It is less valuable in cases of cervical glandular disease, and is entirely uncertain if there is any disease of the annexa.

The Surgical Treatment of Backward Uterine Deviations (Richelot, *Jour. de méd.*, Dec. 8, 1889).—In the treatment one must take into consideration the faulty attitude of the organ, the accompanying lesion of the uterus (metritis) and the lesion of the annexa (salpingo-oophoritis), and pelvic adhesions. In retroversion with adhesions the prognosis is that of salpingo-oophoritis. Slow or rapid rupture of the adhesions, uterine massage, and Alexander's operation should be considered out of the question. The only suitable treatment is that which takes cognizance of the diseased annexa, the faulty position of the uterus being of secondary consideration. Palliative means may be used for the accompanying perimetritis at its beginning, but, if the lesions are rebellious and progressive, laparotomy should be performed and the tubes and ovaries removed. Removal of the diseased annexa and rupture of the adhesions will suffice for a cure without resorting to hysteropexia. In other words, the therapeutics of complicated retroversion is that of the diseases of the annexa and of the pelvic peritonæum. If the retroverted uterus is mobile, it will sometimes suffice to relieve the pain which is caused by the metritis. In other cases pessaries may be used, the round ligaments shortened, or hysteropexy performed. Neither of these methods is certain to produce a cure. Nicoletis has suggested for this condition subvaginal amputation of the cervix, circular incision through the fornices, disengaging the cellular tissue around the inferior segment of the organ, laying bare the posterior *cul-de-sac* of the peritonæum, and securing it by sutures to the straightened uterus. The stump is then secured to the posterior vaginal wall in such a way that the fundus is thrown forward.

The Castration of Women (Tissier, *Jour. de méd.*, Feb. 9, 1890).—This operation was suggested by both Hegar and Battey at about the same time, the object being to produce the menopause prematurely in certain pathological conditions. Thus defined, the operation has an entirely different field from those which are performed for the removal of extensively diseased ovaries and tubes. As is well known, castration of women was practiced ages ago, but not until 1872 did it become an operation of election in and for pathological states. Some of the indications for the operation are troublesome uterine myomata, uncontrollable uterine hæmorrhage, certain conditions of atresia of the genitals, and certain forms of contraction of the pelvis. It is justifiable in certain cases of dysmenorrhœa in which all other forms of treatment have failed to make life less of a burden. The operation is indefensible for neuropathic or disturbed mental conditions, dangerous and inexcusable for the relief of pelvic peritonitis, and criminal for nymphomania. Formerly the incision into the abdominal cavity was made through the vagina, but now the median line of the abdominal wall is universally chosen. Practiced with careful antiseptic precautions, this operation has the minimum of gravity, and Tait has been able to do almost a thousand cases without accident. The menopause results if the ovaries are completely removed, and this result may take place at once or after a few months. In order that there may be an indication for the operation, it is necessary that the trouble to be relieved should have definite relations to the menstrual function, that the age for the natural menopause should not have been passed nor be imminent. It is also necessary that one should first make fair trial of other and less dangerous methods of treatment, and be fairly satisfied of their inutility before proposing castration. This should include in the case of uterine myomata the use of the positive intra-uterine galvanic current, but not the galvano-puncture, which is not useful and is dangerous. For cases in which the hæmorrhage is severe this treatment should be preferred to castration, being fully as effective and less dangerous. Castration is indicated for those tumors in which very rapid growth produces conditions which are constantly and increasingly dangerous.

The Treatment of Endometritis with Chloride of Zinc (Moret, *Jour. de méd.*, Feb. 9, 1890).—1. The vaginal and uterine canal should be cleansed with a solution of sublimate.

2. The cervico-uterine canal should be sounded with a smooth, flexible bougie, which is better for this purpose than the uterine sound, for it is likely to wound the mucous membrane.

3. The bougie having been withdrawn, its curve is to be noted, and then one should introduce a pencil composed of three parts of rye flour and one of chloride of zinc. The pencil should be four to six millimetres in thickness, and should penetrate as far as the fundus.

4. The posterior vaginal *cul-de-sac* should be tamponed with absorbent cotton impregnated with iodoform, and the remainder of the vagina with ordinary non-absorbent cotton.

This treatment may be followed by pain, slight fever, and possibly by transient retention of the urine. In ten or twelve days the slough produced by the caustic will be discharged. After its expulsion the uterine cavity should be dilated with a No. 15 bougie, and the size should gradually be increased to 21 to avoid contraction and dysmenorrhœal pain. During the following month irrigation should be practiced daily with sublimate solution.

A Comparative Estimate of Tait's Method for Perineal Repair (Ott, *Ann. de Obst., Ginecop. y Ped.*, February, 1890).—The Simon-Hegar method for restoring the perinæum is based upon the anatomical conditions of the parts and may be termed the normal method. All the modifications of this method proposed by different authors consist mainly in two particulars: 1st, modification of the shape of the denuded surface; 2d, the manner of maintaining the denuded portions in contact until cicatrization is effected. As to the shape of the denuded surface, the author thinks it should be in each case to the form of the

lesion and the direction of the tear; in other words, that it is impossible to lay down a general rule for operation which would apply in all cases. As to the suturing, he prefers an interrupted suture of silk, using a double row of them. Silk is preferred to catgut, as it is light, easily disinfected, and more durable than catgut. Interrupted sutures enable one to avoid the propagation of infection should suppuration appear at one point, and they are more favorable to union of the tissues, which is a matter of great importance, especially if there is rupture of the intestine. In the complete ruptures the author does not include the intestinal mucous membrane in his suture, and takes up only a relatively small portion of tissue. Successive rows of sutures are passed, and in this way a perinæum is built up which is difficult to distinguish from the normal body.

Tait's method is believed to be contrary to normal anatomical conditions, and hence the advantages claimed for it of simplicity and rapidity of execution have no real value.

Miscellany.

Native Midwifery in Canton.—Dr. Mary W. Niles writes as follows in the *China Medical Missionary Journal* for June:

During a seven years' residence in Canton I have gained an insight into the customs and practices of the Cantonese at childbirth—experiences not confined to any one class, but acquired in the houses of the learned and wealthy as well as in sampans and hovels. Superstition reigns supreme. The woman is placed in a sitting posture over a tub, and constantly urged from the first to bear down. In the case of a primipara, she may thus be deprived of rest and food for several days. Often exhaustion and uterine inertia arise from no other cause. The midwife is constantly shouting that the child is just ready to be born. She spends her time stretching the vulvar orifice. This may be advantageous when her statements are true, but when maintained for hours by relays of midwives, it causes, to say the least, excessive swelling. If there is any delay, the patient is kept in an excited state of mind by neighbors calling and advising this and that, by constant invocations to Kun Yam to save, by burning incense, and drinking tea sent by the idols. A sword and fish-net are laid upon the bed, to drive away the evil spirits. There are also many other idolatrous practices.

The fee to the common classes is $1 for a girl and $2 for a boy; to the poorest class 50 cents for a girl and $1 for a boy.

The midwife has some nice tricks of her own to increase her fee.

She works upon the overwrought mind of the patient by causing her to believe there is some difficulty in the birth that *she* can only overcome, and, unless she has more money, will not stay. The more terror she can inspire, the more gain she expects. I must, however, say that all midwives are not so unscrupulous. I am acquainted with at least four who, with all their faults, have gained great favor in my eyes by always sending for *me* when they get into difficulty. It therefore does not behoove me to speak ill of those who sound my praises to their patients and enjoin a strict observance of my orders—to my face, at least. To proceed, immediately after the placenta is delivered the patient is placed upon the bed and compelled to sit erect. If she can bear it, this is very favorable to the expulsion of clots, etc.; if she can not, some one must assist her. Again, if she becomes faint, it is all the more important she should be held upright. A few months ago I witnessed the efforts made to revive a woman in a condition of syncope after childbirth. I had been called to the case, as one of difficult labor. But when I arrived, the child and placenta were already delivered. The woman was in the usual position. Perceiving that she was not in a condition to endure very much, I requested her to lie down.

When I myself have assisted at labors, my instructions are generally carried out—at least while I am present.

There seems to be a superstition that if there has been foreign interference some dire results may follow disobedience to orders. Once, when I had but left a few moments, a messenger ran after me beseeching me to return, as the patient had fainted. I hastened back and beheld a scene. The very small room occupied by the patient was filled with people. The one window and the two doors were shut. The room was filled with smoke from fire-crackers and the burning of a varnished umbrella. A lighted furnace was also in the room. Besides the noise made by the crackers, all were screaming at the top of their voices, calling to the woman's spirit to return. She was supported by the husband and midwife—one behind, the other before. They had their arms tightly around her, excluding almost every breath of air. A third assisted in holding her head up by keeping a tight grip upon her hair. Finding my voice could not be heard in this tumult, I struck out right and left, and soon made the attendants aware of my firm intention to make them let go their hold, even if it had to be done by force. As soon as she was in a horizontal position she revived. But, before I was aware of it, my efforts were seconded by holding over her face a large Chinese iron cooking vessel, heated for the purpose. Of course this was instantly removed. Immediately after a patient has been placed upon the bed the custom is to give a large bolus containing some very acrid substances, mixed with the juice of fresh ginger, followed by a bowl of rice and salted duck-eggs. The pill and ginger is continued to the second and third day, and afterward "ginger vinegar" is given with the rice throughout the whole of the puerperal month, a large jar of this being always prepared before the birth of the child.

Much importance is attached to the "ginger vinegar," and it is the gravest question as to whether the patient will be allowed to take it. If at the time permission is not given, a day must be set apart when it can be taken. Friends come to me a number of times during the month to know if the "ginger vinegar" may now be given. Some drink a cup of child's urine every day for three days. Having witnessed these pernicious practices, I was surprised, while reading a Chinese book on midwifery, to see how many of them were condemned, and what sensible advice it contained, and given by people, too, who are ignorant of the very mechanism of parturition. I understand the pamphlet in question to be considered an authority. I know not why the educated forego its advice, to follow the superstitious practices of ignorant old women. The book . . . is probably the treatise on midwifery translated by Dr. Lochart. It was fully translated by Dr. Kerr thirty years ago. The Practice of Obstetrics among the Chinese, written by Robert P. Harris, M. D., of Philadelphia, and published in the *American Journal of Obstetrics and Diseases of Women and Children*, July, 1881, drew its information and made extensive quotations from Dr. Kerr's translation. The book evinces the greatest ignorance of the facts of gestation, the mechanism of labor, and the causes of difficulty in the delivery of the fœtus and secundines; yet its mission "to restrain the activity of the midwife, and to educate the people, that she is not in any manner to assist in the delivery of the fœtus," is most laudable.

I will make some extracts, which would be really helpful if native midwives would follow their advice:

"There are three important principles to be borne in mind: 1. Lie down. 2. Endure the pain. 3. Be slow about the delivery. If these rules were obeyed, at least three fourths of the difficulties I have met would have been avoided. The first pains are in the abdomen. The woman should have her mind made up to this as necessary, and not to be feared. If the pains do not increase in severity, she need not inform any one of them, but lie still and be at peace. The foundation of all difficulty lies in sitting over the tub . . . when the pains are but slight."

"When the pains are beginning, the woman should eat and sleep as usual."

"The rapidity of the pains will show the course of the labor. It is most important not to consider the tub and the straw very early, and hence bear down and put pressure upon the abdomen. The body should be kept straight, neither in lying or standing should it deviate to one side."

"The woman should take matters into her own hands, and not allow herself to be governed by others, such as midwives or meddlesome neighbors. This matter is of the greatest importance to herself. She must nourish, and not waste, her strength."

"It is the best plan to go to bed and lie there with eyes closed. If wearied with lying, rise and walk about with the support of friends, and

then return to the bed. The woman should lie upon her back. After prolonged efforts at expulsion, the strength of the fœtus is exhausted, and when the proper time for birth arrives there is no strength for delivery." (Write "mother" instead of "fœtus" and the remark is correct.) "In a case in which the arm or foot presents, direct the woman to lie down. Gently push up the arm or foot. Have her remain quiet for one night, and delivery will be accomplished normally." The author gives a case of shoulder presentation, where he replaced the arm, and the child was born normally the next day. We know that spontaneous evolution or spontaneous version might take place. Last year Dr. Kerr replaced the arm, when spontaneous version took place and the vertex became the presenting part. Certainly the recumbent position and quietness would be most favorable to spontaneous version, and would tend to delay impaction and exhaustion.

"The doubter says, 'Shall we not have a midwife?' Yes, but remember the midwife is *your* servant, and you not *hers*. Midwives are stupid, not acquainted with the doctrines."

"Late, or early, they call upon the patient to exert her strength. They rub the back, and push down upon the abdomen, and call out, 'The head is here.' They pass the hand into the vagina and do injury. All this as though they, and they only, were responsible for the whole matter. Her duty is simply to pick up the baby."

"After the birth it is not necessary to take any medicine. The pill of . . . (rats' kidneys and rabbits' brains) injures the spirits and destroys the blood when the patient is in the weakest condition and least able to bear it. The . . . is very unwise to take, as it impoverishes the blood and gives puerperal fever."

"The diet should be good, but not fat; chicken or duck broth, from which the fat has been removed. No one should be allowed to visit the room. All should be very quiet. Do not pray to the idols in presence of the patient. Let only one midwife be present, and let her sit at one side, not allowing her to interfere with the course of events. If cold, have a fire in the room. If hot, have a pail of cold water to absorb the hot air."

These extracts indicate common sense in the management of labor, and would, no doubt, have greater influence if it were not for the superstitions which are so universally prevalent.

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for July 18th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—										
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.

A Check upon Early Marriages.—"A variety of arguments, based on science, prudence, and economy, have often been urged against the headlong folly of very early marriage. Reasoning of this kind, however, has unfortunately but little influence with such as those who commit the folly in question, for, indeed, it is not reason in any recognizable degree which guides their crude calculations. If it were, the probability of overstrain in childbirth, which is the natural counterpart of early functional activity, of domestic discord and beggary, and their too common social accompaniments, would not be so freely and frequently encountered. These matters are part of the tribute which will always be paid while, for the want of native sense and sound home-training, fancy is allowed to guide one of the most important concerns of life. The one available means of cure for this prevalent evil consists in a just exercise of parental control, but this, we need hardly remind ourselves, is only too easy of evasion. In a case lately reported to the Holborn Board of Guardians, a juvenile couple and their infant, already dependent on the rates, were said to have been married by the Superintendent Registrar on receipt of a forged notice of consent purporting to come from the girl's father. The lesson thus conveyed was not lost on the board, which decided to notify the Registrar-General as to the wisdom of instructing an official to make personal inquiry in all such cases respecting the wishes of the parents in regard to the matrimonial ventures of their children under adult age. The proposal is certainly a sound one, and represents the minimum of justifiable interference on the part of a society which regards its own most natural interests."—*Lancet.*

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

A HISTORICAL SKETCH OF SURGERY, ANCIENT, MEDIÆVAL, AND MODERN.*

By B. A. WATSON, A. M., M. D.,
SURGEON TO JERSEY CITY AND CHRIST HOSPITALS.

It is with us the midday of science. The grandeur of the present completely overshadows the past. Those mighty agents electricity and steam have become the servants of man and readily obey his mandates. The transatlantic cable annihilates space. The modern steamship brings us to our American homes from a city on the Emerald Isle within the short space of six days. The ponderous locomotive engine, breathing and pulsating like a thing of life, drawing a long train of cars freighted with human beings, traverses our broad continent from New York to San Francisco within about the same brief period of time. Are these the noblest achievements of science in our own age? The answer to this question must certainly be given in the negative, since we are fully prepared to show that surgery has kept pace with, if it has not actually led, every other department of science; but the historical treatment of our subject requires us to say adieu for the present to this land of midday brightness, in order to visit that of Egyptian darkness.

It was in this far-off Eastern country, in the northeastern part of the dark continent, that surgery and nearly every other art and science had their birth.

The brightness of this scientific day has passed away and we are now compelled to search for the evidences of her earliest grandeur in a dim light, which confines our researches to the pyramids, temples, tombs, and works of sculpture. But thanks to the Egyptologists who have deciphered the ancient hieroglyphics found on these works of art, and thus afforded us an indistinct and imperfect view of the old pagan civilization. In prehistoric times the practice of surgery at first was unquestionably patriarchal, but, as the inhabitants of the earth increased, the skill of certain individuals in this department became known; and thus they may have established the first monopolies.

Herodotus visited Egypt about the middle of the fifth century before Christ, and was informed by an Egyptian priest that Athothis, the first successor of Menes, founded the palace at Memphis, and, being a physician, was the author of books on surgery.

A medical papyrus in the museum at Berlin, composed under Ramses II (Dynasty XIX), confirms the latter statement. The era of Menes, according to Bunsen, was 3643 B. C.; according to Lepsius, 3893; according to Brugsch, 4455; and according to Mariette, 5004.

Priority in surgical authorship therefore comes down to us bearing an ancient and regal stamp.

The great school of anatomy, surgery, and medicine was founded at Alexandria 300 years before Christ. This famous school of medicine continued to supply the world with surgeons for many centuries. The most eminent among the earlier of the surgeons of this university were Herophilus and Erasistratus. They dissected the human body, and likewise made vivisections on criminals who were placed in their hands by Ptolemy I for this purpose.

Erasistratus was a bold surgeon, who opened the abdominal cavity for the purpose of performing surgical operations on the liver, and also for the extirpation of the spleen. The invention and application of the catheter in cases of retention of urine likewise belongs to him. Herophilus gained the king's favor and secured a position in the Alexandrian school by the reduction of a dislocated shoulder. Here he devoted himself earnestly to the study of anatomy, which to this day bears the impress of his name. Both Erasistratus and Herophilus are enumerated among the most distinguished teachers and authors of their day. The pupils of these eminent surgeons greatly enriched surgery by the introduction of the tourniquet and appliances for the reduction of dislocations of the femur. A pupil of theirs likewise employed an instrument for crushing stones within the bladder.

The ancient status of surgery in Egypt can not be fully shown by historical data, but that it attained a very high standard under pagan rule can not be doubted. Herodotus has informed us that the ophthalmic surgeons were celebrated and practiced at the Court of Cyrus. Ebers interprets a passage in the papyrus which he discovered as relating to the operation for cataract. Surgical instruments for the ear are figured, and artificial teeth have been found in mummies. The further examination of these bodies, which have been preserved from putrefaction for thousands of years in their Egyptian tombs, reveals the fact that bandaging in those ancient times was a fine art, and the well-set fractures certify to a high degree of skill in surgery. In the museum collections of Egyptian antiquities are found lancets, forceps, knives, probes, scissors, cupping-vessels, etc. The walls of temples and monuments are figured with patients undergoing surgical operations. It may be confidently asserted, on the basis of established facts, that Egyptian surgery under the old pagan civilization did not lag behind the other arts and sciences cultivated in that Oriental land. Therefore let us glance hastily at the progress which had already been made in architecture and sculpture. Architecture here attained in this early age a degree of perfection which has not yet been excelled, and in some respects not even equaled, in our own favored times.

In proof of the correctness of this assertion, let us carefully examine the ancient temples, obelisks, and pyramids. Sculpture was here molded with a high degree of accuracy more than two thousand years before the birth of Christ. The sciences of geometry, music, and astronomy are known to have reached a very high standard in the early history of Egypt. The most brilliant era of learning under pagan rule existed about one hundred years before the birth of Christ. The Alexandrian school had then reached the acme of its glory, medicine had been divorced from the priestly rule, and likewise was freed from mysticisms and superstitions. The teachers had been selected because of their

* The president's address delivered before the Medical Society of New Jersey, June 10, 1890.

well-known scientific attainments, and represented not Egypt alone, but the scientific lore of the Orient. These professors were amply pensioned by the Government, and given free access to the largest library in the world; while, for the further stimulation to action of these scientific gladiators, they were required to engage in open debates and other literary trials. Is it therefore strange that this university should have produced a Euclid, whose name is still familiar in every school where mathematics is studied? The advent of Christ produced a struggle between paganism and His followers. The miraculous cures effected by the Son of God and His disciples were death-blows to scientific or rational surgery. The early Christians were a band of fanatical "Faith Curists." This new development produced its natural effect on the Alexandrian University, but still it continued its existence more than six hundred years after the birth of Christ. Consequently the life of this institution was about one thousand years. During this time there had been gathered into its library about seven hundred thousand volumes. In the year of our Lord 640 the city was captured by the Arabians, and the professors fled to various parts of the world to escape death at the hands of their enemies.

Many of the physicians and surgeons went into Italy, which became their future home. This school was the most brilliant gem in the pagan civilization. The surgeons who were trained within her walls while she was at the height of her glory became the peers of kings, and even those educated there after she had entered on her decline were always respected and honored where science could be appreciated. The destruction of this famous school of science was the prelude to the present Egyptian darkness. There is no mention made in the Old Testament of the performance of any surgical operation by the Jews before the children of Israel went into Egypt, where they sojourned four hundred and thirty years; and, consequently, it may be rationally inferred that they learned this art from the Egyptian surgeons. The first reference made to the performance of any operation on the dead or living human body after this Egyptian residence occurred seventeen hundred years before the birth of Christ, when "Joseph commanded his servants, the physicians, to embalm his father, and the physicians embalmed Israel." Circumcision was an operation which was practiced by the Israelites during their sojourn in Egypt. This operation was first performed on Abraham when he was ninety years of age, which was about 1897 before the advent of Christ.

The operation of circumcision was done with sharp Ethiopian stones. In addition to these surgical operations performed by the Israelites, there are also references made in the Scriptures to the following surgical dressings, appliances, and instruments: "An eye salve," "a lump of figs laid for a plaster upon the boil," "an awl for boring the ears," "a roller to bind," as applied to a broken limb, lancets, etc. There are no means known by which it can be determined whether the Jews had made much or little progress in the art and science of surgery after their departure from Egypt; but, after Christ came, the scientific study of medicine was entirely abandoned. The miracles of our Lord, shown in the healing of the sick and the cure of bodily infirmities, led to the belief that the physicians in these difficult and disagreeable processes were all wrong, and that the true remedial mode was by prayer, fasting, and faith.

The earliest history of Greek surgery, like the Egyptian, has its origin in mythological legendry, and one of these legends may possess sufficient interest for my readers to justify me in repeating it here. This interest depends on the fact that representations of the serpent have been for ages and are still variously employed in connection with medical literature. Thus Hygeia, the daughter of Æsculapius and the goddess of health, is represented by an ancient statue in the British Museum as feeding a serpent. I saw, when at Pompeii in 1889, a similar statue standing before the ruins of an old drug-store.* "The mythical origin of Greek medicine selects Melampus as the first who practiced the medical art in Greece, and he is believed to have acquired his skill by a divine revelation. Near his house stood an oak-tree, in whose trunk a serpent made its nest. The servants of Melampus killed the old serpent but their master would not suffer the young ones to be molested, and he fed them daily with his own hands. One day he slept beneath the shade of the oak, and the young serpents, creeping about him, licked his ears. When he awoke he found to his astonishment that he could discern the uses of inanimate things—herbs, minerals, and all dumb animals. He began at once to apply this knowledge to the service of his fellow-creatures, and kings and princes became his patients."

The parentage of Æsculapius, the grandest of all the Grecian deities, is a subject on which all the ancient historians are in perfect accord. They have told us that Apollo was his father, and Coronis his mother. Furthermore, that Æsculapius, like most of the other young heroes of his time, was instructed by the Centaur Chiron in all the arts especially those pertaining to the practice of surgery. Plato has informed us that the skill of Æsculapius was merely confined to the dressing and healing of wounds with herbs proper for arresting hæmorrhage and assuaging pain. "Plutarch asserts that such comprised the whole of ancient Grecian medicine."

The mythical story of Æsculapius possesses for every medical student a high degree of interest, since his name was for ages closely associated with the medical practice of Greece. He was revered by the Greeks as a physician, and at the same time worshiped as a god. The temples of Æsculapius were erected in every part of Greece, and no other deity in Grecian mythology shared with him his medical attributes. These temples served at the same time as hospitals for the sick and places for the worship of this deity.

Among the most magnificent of these temples were those at Epidaurus, Trikka, Cos, Rhodes, and Cnidos. The temple at Epidaurus is supposed to have been erected twelve hundred years before Christ, and was surrounded by an extensive grove of trees, abounding in serpents. These serpents—emblems of health and life—were also kept in all the Æsculapian temples.

There were hung on the walls of these temples tab-

* *A Chronology of Medicine*, edited by John Morgan Richards, p. 3

on which were recorded the name and age of the patient, the disease and its symptoms, and the treatment by which the cure had been accomplished.

These records were the principal source from which medical knowledge was obtained when the Greeks commenced the study of medicine as a science. These temples were at first devoted entirely to the treatment of the sick and the worship of Æsculapius; afterward, in some instances, became the chief medical schools of Greece. The most ancient of these schools were situated at Cos, Cnidos, and Rhodes. The temples were always presided over by the Æsculapiadæ, a sect of priests, the reputed descendants of Æsculapius. The teaching of surgery was not long confined to the descendants of Æsculapius, since Pythagorus, in the sixth century before Christ, established at Crotona a school of medicine, in which Democedes, an eminent surgeon, was trained. It is also thought that some surgical training was given to students in the Grecian gymnasiums. These priests, the Æsculapiadæ, in the selection of sites for the Æsculapian temples and the preparation of the sick for admission, showed a degree of knowledge worthy of an honest surgeon's highest admiration, while, by their constant exhibition of greed and their cunningly devised plans for the deception of their patients, they set an example which could be advantageously imitated by the most unscrupulous quacks of any age.

The temples commonly occupied some elevated and healthy locality, in close proximity to cities, surrounded by pleasant groves, and in the neighborhood of thermal springs or fountains of medicated waters. The sick, prior to their admission, were required to submit to a thorough purification by fasting, ablution, and inunction, while all other persons were rigorously excluded from these temples. Homer added other gems to the crown of the already deified Æsculapius by rendering immortal the names of his sons, Machaon and Podalirius, whom he praised as the grandest of heroes and the wisest of surgeons. The two brothers were at the siege of Troy, which occurred twelve hundred years before the birth of Christ, and participated in this action in their dual capacity.

In Homeric poems their virtues are thus portrayed:

> "Of two great *surgeons*, Podalirius stands
> This hour surrounded by the Trojan bands,
> And great Machaon, wounded in his tent,
> Now wants the succor which so oft he lent."

The treatment of wounds at this early period (about 1200 B. C.) is thus described by Homer, who wrote in the ninth century before Christ:

> "Patroclus cut the forky steel away,
> And in his hand a bitter root he pressed,
> The wound he washed and styptic juice infused.
> The closing flesh that instant ceased to glow,
> The wound to torture and the blood to flow."
> *Iliad*, Book XI.

We learn from ancient history that skillful physicians were highly appreciated under pagan rule; when captured as prisoners of war they were sold into bondage for fabulous prices. In some cases they were admitted as residents to the royal palaces of their captors and rewarded for special services by receiving in marriage the daughter of the ruling sovereign and a portion of his kingdom.

Homer, speaking for the wise and august Nestor, says:

> "A wise physician, skilled our wounds to heal,
> Is more than armies to the public weal."

It must be admitted that nothing like a clear and comprehensive history of Grecian surgery can now be obtained until we come down to the Hippocratic period in the fifth century before Christ. Homer probably possessed some definite knowledge of the surgery of the Trojan period, but his writings, unfortunately, afford us but little of the desired light, and, in fact, they may be fitly compared to the vivid flashes of lightning in a dark night. Here follows a long period—about seven hundred years—of which nothing is known of the surgical progress of Greece. However, it is quite evident that surgical progress during this period was severely embarrassed by the want of an accurate anatomical knowledge. The laws of Greece strictly prohibited the dissection of the human body, and this condition must have been a great obstacle in the way of surgical advancement. Hippocrates (450–351 B. C.) was born on the island of Cos, a famous seat of learning at that time, and he availed himself of all its advantages. In later years, prior to commencing his life's work, he traveled over every part of Greece, spent much time in study at Athens and other seats of learning, and was everywhere assisted by the ablest masters in science and philosophy. In this manner his mind was well stored with knowledge by a long and faithful course of study, while the variety of these studies, aided by the advantages of travel and contact with the brightest minds of earth, had broadened his views and developed his reasoning faculties far beyond those ordinarily found in professional men of his or any other age. *Still, there was something wanting to enable genius to rise to an undying fame. He must know his own power.*

This knowledge was soon revealed to him. A pestilence had seized hold of Athens. He hastened to this city thus threatened with destruction, and succeeded in delivering her from the terrible scourge. The people were grateful for the deliverance, and promptly rewarded him for these valuable services. A golden crown was placed upon his head, and all the rights of citizenship were conferred upon him. These honors and marks of distinction were promptly followed by others from various sources, some of which he accepted and others he declined; but nothing was now wanting to enable him to fulfill man's highest mission, to win for himself undying fame, and at the same time become the world's greatest benefactor. His writings mark in Grecian history a new era—the brightest the world has ever known—and well may he be styled the "Father of Medicine." He died in the ninety-ninth year of his age, free from all disorders of the mind and body, and after death he was designated "*The Great*"—the same honor which was conferred on Hercules. He was the Homer of his profession. The works of Hippocrates were long preserved in the Alexandrian library, and have been handed down to us in such a form that every one who will may read them, and

they prove to us that he was a general practitioner and not a specialist.

"No less than eight of his seventeen treatises now admitted to be genuine works are strictly surgical, . . . and furnish us a very clear insight of the principles and practice of this science and art as it was understood twenty-three centuries ago. . . . When we reflect upon the character and importance of the numerous operations which were then performed, we certainly find more occasion for admiration than we do for adverse criticism. Thus we find that, in the ancient days of surgery, fractures and dislocations were carefully adjusted and reduced; extension and counter-extension were made by ingenious apparatus; the most exact coaptation of fractured bones was insisted upon, as it was considered disgraceful to allow the patient to be maimed with a crooked or a shortened limb. Splints, and even waxed bandages, giving as much fixity, support, and immobility to the parts as is now done by starch and plaster of Paris, were then in use. Hippocrates also gives directions for the suspension of fractured limbs in gutters and slings. The projecting ends of bones in compound fractures were carefully resected. The bones of the cranium were trepanned for fracture with depression of bone, or for the evacuation of accumulations of blood or pus. Abscesses of the liver, and even of the kidneys, were opened with boldness and freedom. The thoracic cavity was explored by rude percussion and auscultation for the detection of fluids, and, when found, paracentesis was performed, as was also done in abdominal dropsies. The rectum was explored by an appropriate speculum; fistula in ano and hæmorrhoids were operated upon; club-feet were adjusted by bandaging and the use of stiff leather and leaden shoes; the bladder was explored by sounds for the detection of calculi; lithotomy was performed by specialists; gangrenous and mangled limbs were amputated; the dead fœtus was extracted with instruments from the uterus; venesection, scarification, and cupping were also practiced in the days of Hippocrates."*

Hippocrates failed to leave behind any distinguished sons or pupils whose names have been handed down in the history of surgery. Aristotle (384–322 B. C.), who lived at a somewhat later period than Hippocrates, added something to the existing knowledge of anatomy. Praxagoras, a distinguished surgeon of Cos—a contemporary of Aristotle—contributed to both anatomy and surgery. He was the first to establish a distinction between the arteries and veins, while in his surgical practice he was bolder than most of his predecessors, since he removed the uvula in inflammatory sore throat, opened the abdominal cavity in those affected with the iliac passion, and replaced the intestines in their normal position. Asclepiades was born at Prussa, in Bithynia, was educated at Alexandria under Cleophantus, and commenced life as a teacher of elocution. He taught in Athens and other parts of Greece, but, having failed in this attempt, he turned his attention to surgery, which he began to practice at Rome, where he flourished as a surgeon and the friend of Cicero about ninety years before the birth of Christ. Here he gained, by the ostentatious display of a little wisdom and much tact, both popularity and wealth. He cultivated most assiduously the friendship of politicians and others having power. Asclepiades was the successor of Archagathus, a Peloponesian, who settled at Rome as a practitioner of surgery about two hundred years before the birth of Christ, and is supposed to have been the first to practice medicine as a profession in that ancient city; but, having given offense to some of its ignorant and superstitious inhabitants, was nicknamed the "*executioner*," and finally banished.

Asclepiades shrewdly avoided the errors into which Archagathus had fallen, studied carefully the foibles and whims of the Romans, and thus enriched himself by appealing to their pride and vanity. He practically discarded the use of all internal medicines, under the pretext that they offended the stomach, and confined himself principally to hygienic measures and the regulation of the diet. The chief remedial agents employed by him consisted in the internal use of wine and a free application of friction to the skin. His comparative ignorance of medicine was in a measure compensated for by his superior knowledge of elocution, which he now turned to a good account by establishing a medical school, in which he became a teacher. He was the first to announce the doctrine of the self-limitation of disease, and declared that the principal cure for fevers was the disease itself. He wrote on ulcers, acute and chronic diseases, and likewise recommended tracheotomy in cases of impending suffocation. In perfect harmony with the many other acts of his life, we are told that he made a wager that he would never be sick, and, if we can believe his biographer, he won even this bet, since he died from the effects of a fall in old age.

The writings of the earliest historians make it apparent that Greece, like every other portion of the inhabited world, had her own charlatans many centuries before the birth of Christ. The Greeks had also in their pay military surgeons; but, according to Xenophon, they were only called after sanguinary battles to dress the wounded. The aleipti, or physicians, sold also secret remedies at the public baths, and were frequently consulted in cases of wounds, etc.

It is self-evident that attempts were made to practice surgery among all the nations of the earth at a very early day; in fact, such efforts were contemporaneous with man's wants. It is equally certain that the knowledge of this art did not make any decided progress among any of the nations until the other arts and sciences were cultivated. It may therefore be confidently asserted that those nations in which the light of general science was first diffused were the first to elevate the standard of surgery. In perfect harmony with this opinion is the fact that in Egypt and Greece the science and art of surgery, as shown by ancient history, soon attained a comparatively high standard, while Persia was dependent on these countries for her surgeons.

The story of King Darius and Democedes (fifth century before Christ) shows that the surgical representatives of these countries sometimes came in conflict with each other. "It happened that King Darius as he leaped from his

* *International Encyclopædia of Surgery*, vol. vi, pp. 114 *et seq.*

horse sprained his foot. The sprain was of no common severity, for the ankle bones were forced out of their sockets."* In fact, it was a dislocation. Now Darius had already at his court certain Egyptians, whom he reckoned the best skilled physicians in all the world; to their aid therefore he had recourse; but they twisted the foot so clumsily and used such violence that they only made the mischief greater. For seven days and seven nights the king lay without sleep, so grievous was the pain he suffered. On the eighth day of his indisposition, one who had heard, before leaving Sardis, of the skill of Democedes, the Crotonian, told Darius, who commanded that he should be brought with all speed into his presence.

When, therefore, they found him among the slaves of Crates, quite uncared for by any one, they brought him just as he was, clanking his fetters and clothed in rags, before the king. As soon as he was entered into the presence, Darius asked him if he knew medicine, to which he answered "No," for he feared if he made himself known he would lose all chance of again beholding Greece. Darius, however, perceiving that he dealt deceitfully with him and really understood the art, bade those who had brought him into his presence go fetch the scourges and the pricking irons (or blinding irons to put out his eyes). Upon this Democedes made confession, but at the same time said he had no thorough knowledge of medicine; he had but lived some time with a physician, and in this way had gained a slight smattering of the art. However, Darius put himself under his care, and Democedes, by using the remedies customary among the Greeks, and exchanging the violent treatment of the Egyptians for milder means, first enabled him to get some sleep, and then in a very little time restored him altogether, after he had quite lost the hope of ever having the use of his foot. Democedes, subsequently, while still residing at the Persian court, added another triumph to that already gained by the successful treatment of a tumor of the breast, under which Atossa, the daughter of Cyrus and wife of Darius, had labored for a considerable period.

There were no medical schools established in Persia prior to the birth of Christ; but the Nestorians, a sect of Christians fleeing the persecutions of orthodoxy, some time in the fifteenth century of the Christian era settled at Edessa, in Mesopotamia, and founded a medical college. This school gained some celebrity. Another body of Nestorians settled in the city of Dschondisabour and established another medical college. It was in this school that the Persians and Arabians studied the healing art during a portion of the Dark Ages. The Hindoo mythology assigns to Brahma the powers of deity and likewise those of a physician, but has most generously attributed to six other minor divinities the power of healing the sick.

It is unquestionably true that surgery in the early part of the Christian era had already attained to a high standard in India, the real question being whether the Greeks got their knowledge of surgery from the Hindoos, through the Egyptian priesthood, or the Hindoos obtained it from contact with the western civilization after the campaigns of Alexander.

It seems to me highly probable that this knowledge came to the Hindoos from contact with the western civilization. The oldest existing book relating in any way to surgery is the *Charaka Samhita*, a bulky encyclopædia, probably composed some centuries after Christ. Another work of at least equal authority, but probably somewhat more modern, is the *Susrata*. The *Susrata* speaks of a single class of practitioners who treated both medical and surgical cases.

The only distinction recognized between medicine and surgery was the inferior order of barbers, nail-trimmers, earborers, tooth-drawers, and phlebotomists, who were outside of the Brahmanical caste. The same author describes more than one hundred surgical instruments made of steel, which include the most important of those now in common use by surgeons. The Chinese seem to have been far behind the Hindoos. Their knowledge of surgery is still of a very primitive character. Their distinctive surgical invention is acupuncture, or the insertion of fine needles into the seats of pain or inflammation. The present ignorance of the Chinese, as well as the ancient, in surgical matters is probably due to their prejudices and superstitions. They are opposed to drawing blood or dissecting the human body, although they are credited with opening boils. The moxa is a great favorite with them, but is employed more frequently as a prophylactic than as a curative agent. The Chinese policy was for ages opposed to any association with the civilized nations of earth; and consequently they debarred themselves from learning much of that which would have otherwise come to them through contact. They are, or have been until very recently, entirely without medical schools.

History fails to show that there has been in any age any attempt to teach medicine. The Japanese did nothing for the advancement of surgery during ancient times; in fact, all that has been said of the Chinese is equally applicable to them. Rome was settled about seven hundred and fifty years before the birth of Christ, and remained about six hundred years without either physicians or surgeons, trusting entirely during this long period, for the cure of diseases and wounds, to spells and incantations. Public edicts were issued against the professional practice of medicine and surgery during this period, while the public were encouraged to put their faith in traditional prescriptions and religious rites.

Cato, the first Censor, gravely wrote down the mystic words of incantation for curing dislocations and fractures of bones. Rome produced a surgical author, who lived during the Augustan period (30 B. C.–14 A. D.), whose writings have been handed down to us, and constitute the most perfect record in our possession of ancient surgery. The era in which he lived was the grandest period of the Roman Empire and gives us in literature the immortal names of Virgil, Horace, Ovid, and Celsus. The writings of Aurelius Cornelius Celsus likewise serve as a connecting link between the Hippocratic period and the early part of the Christian era, showing the marked progress which had been

* *History of the Heroes of Medicine*, by Russel, pp. 2 *et seq.*

made during the preceding four hundred years. In these writings we behold the mighty influence wielded by the Alexandrian school on the science and art of surgery. In fact, the author shows perfect familiarity with both Greek and Egyptian surgery. Celsus has carefully described the operation for cataract, plastic operations on the ears, lips, nose, etc. Likewise the removal of nasal polypi and the plugging of the nostrils for the control of hæmorrhage. In addition to these operations, he described the method employed for the extirpation of bronchocele, the differential diagnosis of umbilical tumors and omental and intestinal hernia, and the treatment of the latter with pads and bandages. He also mentions the suturing of the intestines, treatment of hydrocele, varicocele, phimosis, stone in the bladder—operative method employed, etc.

These writings by Celsus show a marked advance in the performance of amputations of the extremities since the Hippocratic age. Hippocrates informs us that these amputations were only made through the dead parts lest the patient should die from loss of blood. Celsus gives directions for the performance of these operations through the living tissues, and describes ligation of the arteries as the most potent means known for the control of arterial hæmorrhage.

It should be here understood that I have enumerated only a limited number of the surgical operations which Celsus has described so lucidly, and the modern surgeon may be confidently assured that these surgical writings are still worthy of a careful perusal.

Soranus, surnamed the younger, a native of Ephesus, a distinguished pupil of the Alexandrian school, located at Rome, under the reign of Trajan and Hadrian (98–138 A. D.). The works of this distinguished author have perished with the exception of some fragments which have been handed down to us. In his treatise *De utero et pudendo muliebrie* he gives a lucid description of the differential diagnosis of pregnancy, ascites, and solid tumors by the aid of percussion, palpation, and succussion; and likewise mentions the use of the vaginal speculum and the uterine sound. He also wrote a treatise on fractures, a portion of which is still extant.

Antyllus, a distinguished Italian surgeon and author, flourished in the latter part of the first or in the early part of the second century. The greater portion of his works have perished, but fragments have been preserved in the quotations of subsequent writers. He was the first to recommend bronchotomy in cynanche, arteriotomy instead of venesection, etc.

Galen, whose writings were regarded as the highest authority for more than thirteen hundred years on medical topics, was a physician rather than a surgeon. He was born at Pergamus, in Asia Minor, about one hundred and thirty years after the birth of Christ, settled in Rome, where he won the highest fame, in the year one hundred and sixty-four, but remained there about five years, when he returned to the land of his birth, where he died about 200 A. D.

The most worthy surgeons who graced the decline of the Roman Empire were Oribasius (350 A. D.), Aetius (400 A. D.), and Paulus Ægineta (420 A. D.). These were all compilers rather than original authors.

The surgery of Oribasius is characterized by timidity and shows no progress since the Hippocratic period. We have reached a period when amulets, charms, and incantations were employed in the place of rational means for the relief of surgical cases. Thus Aetius, in composing a certain ointment, required that there should be repeated in a loud voice, "*May the God of Abraham, the God of Isaac, and the God of Jacob deign to accord virtues to this medicine*"; and, when a foreign body had lodged in the gullet, recommended that the neck of the patient should be touched by the surgeon, who at the same time exclaims: "*Get thee out or descend, the martyr Blaise, Servant of Jesus Christ, commands thee.*"

The writings of Aetius, like those of Oribasius, contained only extracts from the older surgical authors; and these were interwoven with the grossest bigotry and superstition —products offered by Aetius in the place of scientific knowledge and rational conclusions.

There is much difference of opinion among the old historians in regard to the age in which Paulus Ægineta lived and wrote; and at this day it is probably impossible to fix it with any degree of certainty. Some authorities believe it was as late as the seventh century of the Christian era, while others think it was as early as the fifth.

His writings are similar in most respects to those of Oribasius and Aetius, but possess some original and valuable information. He was educated at Alexandria, and is supposed to have been a professor in that city. His work presents an able and orderly summary of Greek medicine from Hippocrates downward. This author, in his published work, draws from many sources, and much from his own personal experience.

We have now traced the history of surgery from its mythological origin in Egypt, and from the cloud-capped Olympus, the habitation of the gods in Greece; we have watched it loitering in primitive purity about the temples of Æsculapius, till it found its onward way to Rome, where, polluted by the filth of that vicious metropolis, we have seen it converted into a diabolical system of charlatanism—reason and experience banished, ignorance and superstition re-established—where charms, amulets, and sacrilegious incantations take the place of scientific knowledge; in this degraded state it falls into the hands of the so-called Christian priest physicians, after it had been rescued from the pagan priesthood by the efforts of Hippocrates and the Alexandrian school of medicine.

The dark age of surgery is thus ushered in, but the darkness steadily increases during the next eight or nine hundred years. During this period there were no distinguished surgeons, and nearly all which had been previously learned of this science and art was forgotten. It was principally in the school of Salernum that even a flickering light was maintained. The University of Salerno was founded in 1150, and was long one of the greatest seats of learning in Italy. It appears from history, however, that Salerno, even prior to this date, was entitled to some consideration as a city of medical learning, since at the end of the seventh century it was the seat of a Benedictine monastery, and that

some of the prelates and higher clergy were distinguished for their medical acquirements. But it has been, by recent researches, clearly established that the celebrated "*Schola salernitana*" was purely a secular institution. It is therefore certain that the school of medicine gradually grew up, since, at the end of the ninth century, Salernian physicians were already spoken of and the city was known as "*Civitas Hippocratica.*"

At a later period we find great and royal personages resorting to Salerno for the restoration of their health, among whom was William of Normandy, afterward the Conqueror. The Jewish element appears to have been important among the students, and possibly among the professors. The reputation of the school was great until the twelfth or thirteenth century, when the introduction of Arab medicine was gradually fatal to it.

The foundation of the University of Naples and the rise of Montpellier also contributed to its decline. About the middle of the eleventh century the Arabian medical writers began to be known by Latin translations in the western world.

Constantinus Africanus, a monk, was the author of the earliest of such versions (1050 A. D.). His labors were directed chiefly to the less important and bulky Arabian authors, of whom Haly was the most noted. During this period the translation of the works of the old masters in medicine was pushed forward, compendiums from the same source were prepared, but none of the books contained any original matter, nor were the selections always well chosen. In surgery this period was much more productive than in medicine, especially in Italy and France; but the limits of our subject only permit us to mention Gulielmus de Saliceto, of Piacenza (about 1275), Lanfranc, of Milan (died about 1306), Guy de Chauliac (about 1350), and the Englishman, John Ardern (about 1350).

The above-named authors contributed somewhat to the advancement of surgery, or at least helped to stay the tide which was so surely bearing it away. They possessed sufficient independence to oppose the charlatanism of the greedy "Faith Curists" in the Roman priesthood, and taught the importance of clinical observations and rationalism in the practice of surgery. The science and art of surgery had at this time reached its lowest degradation. The priests had entirely abandoned the precepts of the old masters in surgery, and professed to cure all sorts of injuries by use of the so-called sacred relics, charms, amulets, etc. The most absurd reports were made of miraculous cures, attested by monks, abbots, bishops, popes, and consecrated saints. They alleged that they had restored the blind, the epileptic, the insane, etc. "The Saints of the Romanists have usurped the place of the Zodiacal constellations in the government of the parts of man's body; for every limb they have a Saint. Thus St. Otilia keepes the head instead of Aries; St. Blasius is appointed to governe the neck instead of Taurus"; and so old Melton goes on to the end of the list. Pettigrew gives the names of nearly fifty Roman Catholic saints who were believed to have special control over certain individual diseases, both medical and surgical. The priesthood also assigned saints to wells and springs to give healing virtues to these waters, and instituted health-seeking pilgrimages to these places.*

This evil had become so firmly rooted that it required the best efforts of the Popes and Holy Councils for nearly one hundred years to remove surgery from the vile hands into which it had fallen. The first mandate against this practice was issued by the Lateran Council, under Pope Callestus II, A. D. 1123, while, "in 1215, Innocent III fulminated an anathema specially directed against surgery, by ordaining that, as the Church abhorred all cruel or sanguinary practices, no priest should be permitted to follow surgery, or to perform any operations in which either instruments of steel or fire were employed, and that they should refuse their benediction to all those who professed and pursued it." †

It is unquestionably true that the priest surgeons, on account of the opposition in the Roman Church, were at first influenced to employ barbers to perform surgical operations under their directions, although the practice had its origin in the early part of the tenth century, while the final edict which compelled this course was not promulgated until the first part of the thirteenth. The barber surgeons, having learned something of the art of surgery from the priests, finally usurped the entire practice.

Well may the surgeon of the present day thank God that his lot has been cast with intelligent *confrères* rather than with the barber surgeons, of whom Thomas Gale, an English military surgeon, said in 1544: "I remember when I was at the wars of Muttrel, in the time of that famous prince King Henry VIII, there was a great rabblement there that took upon them to be surgeons. Some were sow-gelders and horse-gelders, with tinkers and cobblers. This noble set did such great cures that they got themselves a perpetual name, for, like as Thessalus's sect were called Thessalanians, so was this rabblement for these notorious cases called dog leeches; for in two dressings they did commonly make these cures whole and sound for ever after." ‡

History informs us in the following language that King Henry VIII and his Parliament, in the third year of his reign, *restrained the practice of both* (medicine and surgery) by the following act: "To the King our Sovereign Lord, and to all the Lords spiritual and temporal, and Commons in this present Parliament assembled: For-as-much as the science and cunning of physick and surgery (to the perfect knowledge whereof be requisite both great learning and ripe experience) is daily, within this realm, exercised by a great multitude of ignorant persons, of whom the greater part have no manner of insight in the same, nor in any other kind of learning; Some also can no letters on the book so far forth that common artificers, as smiths, weavers, and women, boldly and accustomably take upon themselves great cures, and thing of great difficulty, in the which they partly use sorcery and witchcraft, partly apply such medicines unto the disease, as be very noious, and nothing meet therefore, to the high displeasure of God, great infamy of

* *International Encyclopædia of Surgery*, vol. vi, p. 1181.
† *Ibid.* ‡ *Ibid.*, p. 1189.

the faculty, and the grievous hurt, damage and destruction of many of the king's liege people, most especially *them that can not discern the uncunning from the cunning: Be it therefore to the surety and comfort of all manner of people*, by the authority of this present parliament enacted, that no person within the city of London, nor within seven miles of the same, take upon him to exercise or occupy as a physician or surgeon, except he be first examined, approved and admitted by the bishop of London, or by the dean of St. Paul's for the time being, calling to him or them four doctors of physick, and for surgery, other expert persons in that faculty; and for the first examination such as they shall think conveniant, and afterwards always four of them that have been so approved, upon the pain of forfeiture, for every month that they do occupy as physicians or surgeons not admitted or examined after the tenour of this act, of five pound, etc." *

These extracts present a faithful picture of the degraded condition of surgery in the hands of the barber surgeons, to whom it was principally confided until about the middle of the seventeenth century, while the use of the sympathetic powder of Sir Kenelm Digby affords us a glimpse of the irrational methods employed in the treatment of wounds. "Whenever any wound had been inflicted, this powder was applied to the weapon that had inflicted it, which was, moreover, covered with ointment and dressed two or three times a day." Fortunately for the science of surgery and humanity, during the whole period in which the practice of surgery was monopolized by the barber surgeons there were a few scientific and bold spirits, who kept alive the flickering sparks of an almost forgotten science. Among this number must be mentioned Mondini de Luzzi, a professor of anatomy at Bologna, who dissected the human subject before his class in 1315—a feat which had not been previously performed during the Christian era. He likewise composed a work on anatomy, which continued to be used in all the medical schools of Europe for about two centuries.

This bold and successful example was imitated by other teachers. The dissection of the human body once more placed surgery on a firm basis, and it has continued to progress both as a science and an art to the present time. It was not, however, until the first half of the sixteenth century that there appeared one greater than himself, and whose labors far excelled those of this noble pioneer.

Andreas Vesalius was born in 1514 and died in 1564. He became, when twenty-two years of age, a professor of anatomy in the renowned University at Padua, where he lectured to large classes of students. He published in 1543 by far the most splendid work on anatomy the world had ever seen. Thus it was that he surprised the world and immortalized his name. There was born at Laval, in the province of Mayenne, France, about 1509, the most famous surgeon of his age, Ambroise Paré, who did more for the advancement of surgery than any other that lived during the sixteenth century. He inherited from his parents poverty, a strong constitution, lofty ambition, and a strong will-power. This inheritance secured for him in after life a royal recognition among men of science and the rulers of his country.

In boyhood he was apprenticed to a barber surgeon, from whom he learned the rudiments of minor surgery. Having come in contact with Germain Colot, a distinguished lithotomist, whom he greatly admired for his skill and dexterity, the young barber surgeon determined to go to Paris in order to further perfect himself in surgery. He served three years at the Hôtel Dieu as a house surgeon, and was appointed a military surgeon at the age of twenty-seven, in which capacity he rapidly rose to the highest rank in the French army. It was in this service that he so greatly distinguished himself as a close observer and rational practitioner. He rendered special service to the profession by the re-introduction and popularization of the ligature, by discarding the senseless and barbarous treatment of wounds with boiling-hot oil, by improving the hygienic surroundings of the wounded—which action was, at this early day, based on the discovery that the atmosphere of hospitals, camps, etc., contained some septic agent which exerted a deleterious effect on open wounds.

He likewise rendered great and permanent service to surgery as an author, and these books still remain and speak to the profession, although the hand which penned them has long since returned to dust. This distinguished surgeon died in 1590, full of years and crowned with honors. The grandeur of his labors has immortalized his name. Humanity owes him a debt which it can never repay, and may the rising generation of surgeons imitate his noble example, and thus erect a monument to their names which can never be destroyed by vandalism.

It may be observed, in rapidly passing over the history of the sixteenth century, that certain events which had occurred during the fifteenth century served to awaken thought and pave the way for the rapid progress made in the arts and sciences during Paré's time. Thus the discovery of printing became the hand-maiden for the diffusion of knowledge. The dissection of the human subject supplied the requisite anatomical knowledge for the intelligent performance of surgical operations. The establishment of medical schools in various parts of Italy—particularly those of Padua and Bologna—afforded an opportunity for students to congregate together for the purpose of receiving instruction and stimulated the professors to greater activity in their teachings.

Thus we find that Montagnana, a professor at Padua, in 1460, who cultivated anatomy, boasted of having opened fourteen subjects, a thing quite remarkable for his time, while Leonard Bertapaglia, a professor of surgery at Padua, published a commentary on the fourth book of Avicenna, which is characterized for its classical lore, but not otherwise above the barber surgery of the times, since his surgical theories are filled with absurdities. Another professor at Padua, Alexander Beneditti, is said to have contributed greatly to the improvement of anatomy and surgery in Italy toward the end of the fifteenth century.

It was likewise during this century that the operation was devised for the replacing of the nose when lost by ac-

* *The Unity of Medicine.* By F. Davis, London. Pp. 48 *et seq.*

cident or disease. This operation was first performed by three Italians—Vincent Vianoe, Branca, and Bojani. It was afterward improved by Tagliacozzi. The treatment of gunshot wounds in the sixteenth century was greatly improved by Maggi Leone, a professor at Pavia; Botal, a celebrated anatomist; Felix Wurz, a German surgeon; Guillemeau, a pupil of Paré; and others. Besides the anatomists and surgeons already mentioned, among the distinguished in the profession in this century there should be added the following names: Fabricius Hildanus; Berenger de Carpi, who dissected more than one hundred subjects; James Dubois, who Latinized his name Sylvius, and was the master of the great Vesalius and the true founder of anatomy in France, and also the first who injected the blood-vessels. Likewise Eustachius, who discovered the Eustachian tube; Gabriel Falloppius, who first described the Falloppian tube; Fabricius ab Acquapendente, who first described the valves of the veins; and, lastly, Michael Servetus, who comprehended the circulation of the blood through the lungs; but it was reserved for Harvey at a later date to discover the general circulation.

The seventeenth century was not marked by any grand advance in surgery; but several discoveries were made which have since contributed to the material progress of this art and science. Thus the discovery of the general circulation of the blood by William Harvey in 1619 has brought forth valuable results. Malpighi, of Bologna, soon afterward supplemented Harvey's discovery by microscopically demonstrating the course of the blood-corpuscles in the minute blood-vessels, and the communication between the veins and arteries. History informs us that "burning spheres," as they are termed by Aristophanes, were sold in the shops of Athens in his day—about 400 B. C.

There is no evidence that lenses were employed at this early date for magnifying, at least otherwise than as reading-glasses. It is not until the seventeenth century that we find powerful magnifiers of glass actually employed for scientific investigation. The names of Malpighi, Lieberkühn, Hooke, Leeuwenhoek, Swammerdam, Lyonnet, and Ellis are closely connected with the history of the simple microscope.

The use of this instrument has proved to be a most powerful adjuvant for the advancement of surgery, since it enables us to study the minute tissues of the body, and thus understand the nature and difference between histological and pathological elements. During this century there was considerable progress made in the study of anatomy, and among the names which were made illustrious by these researches in the anatomical field may be mentioned that of Schneider, a German anatomist and writer, whose name is associated with the mucous lining of the nose; Francis Glisson, memorable for his researches on the anatomy of the liver; Peyer, who studied carefully the glands of the intestines; Meibomius, who studied the anatomy of the eyelids; Thomas Willis, who studied the anatomy of the brain; while Stenson and Wharton studied the anatomy of the glandular system.

Surgery made little progress during this century, owing principally to the fact that it had not yet been taken from the hands of the barber surgeons and elevated to the standard which it now holds among the professions. England, however, produced during this period some surgeons whose names are worthy of mention, although they are scarcely entitled to be considered illustrious. Among these were Richard Wiseman, author of a book on surgery, and James Young, an English surgeon of Plymouth, a contemporary of Wiseman, who published a treatise on several surgical subjects at London in the year 1679.

The eighteenth century was not characterized by any remarkable progress in surgery, although the tendency was in the right direction. There was, in fact, some marked improvement made in the treatment of gunshot wounds. (The discovery of gunpowder and the use of firearms in war marked a new period in military surgery; but the date of this innovation has never been satisfactorily settled. It is, however, fully established that it was employed in the early part of the Christian era. The soldiers were horrified at the enormous increase in the mortality attending a battle, while the surgeons were unable, in their ignorance of scientific wound treatment, to render any important service. Under these circumstances the wounds were soon declared to be poisoned with the gunpowder and ball, and the surgeons and soldiers united in thinking that this mighty agent was the power of hell and had been invented by the devil.) The old and cruel treatment which had been introduced by John de Vigo and others, based on the supposition that every gunshot wound contained a poisonous substance, even in its primary condition, and therefore must be treated by pouring boiling hot oil into it, was entirely abandoned.

The cumbrous dressings which had been previously in vogue were entirely superseded and more rational means were employed in the treatment of wounds. The numerous European wars of this century gave an abundant opportunity for the study of gunshot wounds. "The degrading association of the barbers and surgeons was abolished in 1743 at Paris by an edict breaking the legal fetters which had for so many years bound together the surgeons of St. Cosine and the barbers, and the example was speedily followed in 1745 by a similar act of the English Parliament. Freed from this galling servitude, surgery became a separate and distinct branch, to be ever afterward studied and cultivated by educated members of the profession." Prior to this date surgery had not been taught in the medical schools during the Christian era; but in this century surgical professors were appointed in Holland and Germany. The study of anatomy, which had made very rapid progress during the two preceding centuries, still continued to engage the attention of anatomists in every part of Europe. Duverney, during the latter part of the seventeenth century, had established the identity of the chyliferous and lymphatic vessels, Pacchioni had discovered the lymphatic glands of the dura mater, and Cowper the two glands which have since borne his name.

It was during this century that anatomists studied carefully the anatomy of the brain, nerves, eye, and ear. Pacchioni and Baglivi gave their attention to the brain, but the result was entirely negative. Tarin Le Cat and Meckel

studied the cranial nerves with satisfactory results.* "It had already been established in the seventeenth century that the seat of cataract was the crystalline lens, and Morgagni now described the humor in the midst of which it was nourished. Experiments were also made by Petit in regard to the nerves of the eye, the effect of age in producing changes in the organ, etc.; and Albinus and Haller each professed to have discovered the pupillary membrane. The two anatomists, however, who accomplished most at this time in perfecting the study of the anatomy of the eye were Porterfield, of Edinburgh, and Zinn, of Göttingen, each of whom ascribed important functions to the ciliary process. The structure of the membrana tympani and the distribution of the auditory nerve had been accurately studied a few years before the commencement of the eighteenth century; but Valsalva now described much more precisely the minute portions of the ear, and of the labyrinth especially, the use of the fluid of which was afterward discovered by Cotunnius and Meckel." †

Important results were obtained during this century, by the study of the lymphatics, by Cruikshank, Hewsen, Paul Mascagni, and William and John Hunter. The study of pathological anatomy now commenced in all the European countries, with which the name of John Baptiste Morgagni is still intimately connected, having been perpetuated by the work which he prepared on this subject. The surgeons of the eighteenth century whose names have been handed down to us were the following: John Hunter, Jean Louis Petit, Laurence Heister, Percival Pott, Pierre Joseph Desault, William Cheselden, Sir James Earle, Henry Francis Le Dran, and Chopart. The first named in this distinguished galaxy of illustrious men was unquestionably the most distinguished anatomist and surgical pathologist of his era. He was born of Scotch parents in 1728, and died in 1793. Poverty, ignorance, energy, an indomitable will-power, and a robust constitution were his inheritance. His father had died when young Hunter was only two years old, and his mother, although a strong-minded woman, had failed to exercise much influence over him. He went to London when about twenty years of age, where his elder brother, William, had been living some time. At that time Dr. William was doing a large and lucrative practice and rapidly gaining in reputation. The meeting between the brothers was cordial, and John was given the position of assistant in William's anatomical rooms, which were then in their infancy, but rapidly growing in favor on account of the educational advantages which they offered to students. The high position which Dr. William Hunter had already attained in the great metropolis stimulated his brother John to put forth all his latent or undeveloped energies, in order that he too might at some future time become a power among men. Ignorant and poor as he was at that time, the indomitable will-power, supported by energy and a robust constitution, absolutely settled the question in favor of success, since with such persons "to will" is to do. He pressed forward, soon acquired a thorough knowledge of anatomy, and acted as his brother's prosector for his anatomical lectures. He spent the summer of 1749 at the Chelsea Hospital, under the instruction of the celebrated Cheselden, who was then nearing his grave; and in 1751 he became a pupil at St. Bartholomew's, where he received instruction from the renowned Percival Pott, another luminary of British surgery.

It was at this time the desire of his brother William that John should become a physician rather than a surgeon. With this objective view, John was persuaded by William and other friends to enter as a student St. Mary's Hall, Oxford, in 1753. He remained there but a short time, having now fully determined that he would spend no more time in the study of Latin and Greek.* He looked upon such studies as a waste of time; and, in referring to the subject some years afterward, he thus feelingly expressed himself: "They wanted," he said, "to make an old woman of me, or that I should stuff Latin and Greek at the university; but," added he, significantly pressing his thumb-nail on the table, "these schemes I cracked like so many vermin as they came before me." One can not but regret that Hunter did not carry out the wishes of his friends. A little "stuffing" of Latin and Greek would have been of vast benefit to him in preventing those errors of style and literary composition which so greatly disfigure and obscure his writings.

Hunter once more returned to his surgical studies, and we find him at St. George's Hospital in 1754, where two years later he was appointed a house surgeon. He, however, occupied this position only for a brief period, when, having received an appointment as staff surgeon, he went with the army to Belleisle, an island off the western coast of France, while the following year he participated with the English army in the Peninsular war. He returned in 1763 to London and resumed the practice of surgery, having profited greatly by his extensive military experience.

He added steadily from this date new laurels to those which he already possessed, gained in reputation and power, and soon after became recognized as the greatest surgeon of his age. His surgical writings show him to have been possessed of considerable originality and most excellent powers of observation. He wrote a *Treatise on Venereal Disease*, and likewise a *Treatise on the Blood, Inflammation, and Gunshot Wounds*. The former work contains such a clear and accurate description of the primary lesion of syphilis that it has since continued to be known as the true or Hunterian chancre.

The most distinguished surgeon of France in the eighteenth century was Jean Louis Petit, the inventor of the screw tourniquet, still in common use. He wrote the first *Treatise on Diseases of the Bones*, which was soon translated into several languages. Another French surgeon, Pierre Joseph Desault, who lived during the latter part of this century, did much for surgery. He invented many surgical instruments and appliances, some of which are still used and continue to bear his name. It is likewise claimed that

he was the first to give a systematic course of lectures on surgical anatomy, and clinical lectures on general surgery.

A *General System of Surgery*, written by Laurence Heister, who was born at Frankfort-on-the-Main in 1683 and died in 1758, has rendered his name illustrious and kept it from perishing to the present time. He gained the reputation of being an accomplished army surgeon during the war between the French and the Dutch in Flanders, which lasted from 1707 to 1709. This work on general surgery was handsomely illustrated and published in several languages.

The distinguished English surgeon and author, Percival Pott, who was born in 1713 and died in 1788, gave us some of the most valuable contributions ever made to surgical pathology and practice.

His *Chirurgical Works* are contained in three handsome octavos. His classical and vivid description of caries of the vertebræ and spinal curvature caused his name to be affixed to this morbid condition. Pott's disease of the spine can never be forgotten while the English language is spoken or read.

We have traced our noble profession from the dim mythological ages, when the gods alone were supposed to possess the power of healing the wounded, down through the pagan civilization to the formation of the Alexandrian school, which, one hundred years before the birth of Christ, shed a grand meteoric light over the world, the true effulgence of a grand science; have followed it through the dark ages, when it struggled fiercely against the ignorance, greed, and fanaticism of the "Faith Curists," and likewise against the wicked superstitions of a belligerent and benighted populace; have pointed out the beacon lights which were erected by our *confrères* in mediæval times, and have now reached the commencement of the nineteenth century, the brightest period which has ever had an existence since the world was created. We stand in the position of a traveler who has wandered through the virgin forests, beheld the grandeur of an ancient Oriental city, traversed the quagmires of a dark and dismal swamp, emerged into a rural and sparsely settled district, where he beheld an occasional flickering light; but, pressing forward, he now stands within the suburbs of a great metropolis, where he beholds, by the aid of the brilliant electric lights, the grandest structures erected by modern civilization.

Would that I possessed the power of a Homer, Virgil, or Milton, that I might immortalize these men who have made surgery what it is in 1890; but, alas! I have neither the power or space in which to do justice to the many grand heroes of the present age, and must therefore content myself by merely mentioning the names of a few who have been the pioneers in the grandest work the world has ever known. The names Dupuytren, Roux, Lisfranc, Velpeau, and Nélaton, of France; Abernethy, Cooper, Brodie, Fergusson, and Laurence, of England; Colles and Hamilton, of Ireland; Bell, Syme, Liston, and Simpson, of Scotland; Graefe and Rust, of Germany; Scarpa and Porta, of Italy; Physick, Mütter, Pancoast, S. D. and S. M. Gross, of Philadelphia; Wright Post, Kissam, Rodgers, Watson, Stevens, Mott, Van Buren, Parker, Sands, Wood, Little, Carnochan, A. C. Post, and Sims, of New York; Nathan Smith, of New Haven; the Warrens and Hayward, of Boston; N. R. Smith, of Baltimore; Warren Stone, of New Orleans; Dudley, of Lexington; Brainard, of Chicago; Eve, of Nashville; Hodgen, of St. Louis; and James Cabell, of Virginia, are now numbered with the noble dead, while there yet remain with us some of the grandest, noblest pioneers, and most distinguished surgeons the world has ever known. I can not, therefore, do justice to the surgical progress of this century without mentioning these names. Among this long list of distinguished names I can not refrain from mentioning some of our European *confrères*, although I shall enter more fully on the work done by Americans, since we all naturally feel an especial interest in our countrymen. Germany has produced during this century some of the most distinguished surgeons the world has ever known, and among those names already immortal are Virchow, who has given us the best work on *Cellular Pathology;* Billroth, the best on *Surgical Pathology;* and Esmarch, the best *Hand-book on Military Surgery.* However, the fame of Billroth and Esmarch does not by any means entirely rest on these valuable publications, since the boldness and originality of their surgical procedures have likewise electrified the world.

The commencement of this century found America without any really distinguished surgeon, without a surgical literature of her own, and without colleges in which to educate her own students. She was at this period almost entirely dependent on Great Britain for the education of her sons in medicine, and our medical literature was likewise principally obtained from the same source. It is likewise true that in no part of the civilized world had surgery reached a high degree of perfection, but America had just emerged from a long revolutionary struggle and started forth among the independent nations—she was now compelled to provide for her own wants. This fact undoubtedly prompted her to put forth her best efforts. The trying ordeals through which the colonies had passed in their long and murderous wars with the Indians, followed by the revolutionary struggle of seven years war with England, had produced a bold and hardy race of pioneers, who were prepared to attempt anything which offered even the slightest chance of success. The women possessed fortitude and courage, and were prepared to suffer pain, if it only offered an adequate reward. It is not therefore surprising that in the autumn of 1809 Mrs. Crawford, who was suffering from an ovarian tumor, approached the unpretentious house of Dr. Ephraim McDowell, at Danville, Ky., and there submitted to an ovariotomy—the first operation of this kind *ever performed*, but an operative procedure which has already been repeated many thousand times with the most happy results. Mrs. Crawford recovered and lived many years in the full enjoyment of health and with entire freedom from pain. This operation was subsequently repeated several times by Dr. McDowell, who, we are informed, saved the lives of eleven patients out of thirteen. Thus began an operation which has added thousands of years to the lives of civilized women, and saved them from untold misery. McDowell, however, did not escape the sad fate which awaits

every bold innovator in science. His fate in this respect was no better than that of the immortal Jenner, who was assailed by his own professional brethren, the ministers of the gospel, and the public press. Poor McDowell carefully prepared a report of this operation for publication in a medical journal which was edited by a personal friend and professional brother, carried it to him with his own hands, and requested this *now unknown* distinguished functionary to publish the same. The manuscript was in due time returned to the immortal McDowell, to whom it was suggested in a very friendly way that he ought never again to attempt the performance of this barbarous operation, the which had not even been recommended by the most distinguished surgeons of the world. It was likewise added by this friend and distinguished editor that the "publication of your report of this case would endanger the safety of my journal and be ridiculed by the entire profession." This rebuff probably deterred him for a time from making any further attempts at publication, since the earliest publication made by him on this subject was in 1817. The performance of this operation was at first ridiculed in England, but soon afterward he was given full credit for the same. Thus time rights these grievous wrongs and genius receives its just reward.

It was not until near the middle of the nineteenth century that the grandest achievement recorded in all history was consummated by the discovery of a potent and, at the same time, comparatively safe anæsthetic, which enabled surgeons to say to the most horrible agonies attendant on the performance of surgical operations "Begone!"-when his words were promptly followed by a deep sleep, as if uttered by Jehovah himself, and the same condition continued at the will of the operator until the operation was completed.

The patient is then called back to life—a performance which approximates even, in the grandeur of its power, the miraculous raising of the dead. No discovery ever made in the arts or sciences possesses a value which can in any way be compared with that of chloroform and ether. It is *the priceless gem* to suffering humanity. What would not a rational man pay for the relief which these agents afford during the performance of a painful surgical operation? The king would surrender his realm if this priceless boon could not be obtained for a less consideration under such circumstances, and the miser would give up his life-long hoardings for it. Let, therefore, the names of Morton and Simpson go down to future generations as the greatest discoverers known in the world's history. Their services to humanity are far more valuable than those of any other discoverers, inventors, or heroes who have lived in any age.

Priority in this grand work belongs to America, since Morton discovered and popularized the use of sulphuric ether as an anæsthetic in 1846, while Dr. Simpson did the same for chloroform in 1847. The use of these agents during the performance of surgical operations marks the commencement of the grandest epoch in surgery. The anæsthetic enabled the surgeon to perfect and make successful the old operations, while it opened the field for the performance of new ones, which could never have been undertaken without the use of this agent. It enabled the scientific investigator to go forward with his vivisections without giving pain. It likewise in this case greatly increased the field of labor, and added at least fourfold to the previous value of these investigations. Brain surgery, abdominal surgery, and gynæcology, which are essentially new departments in the surgical field, could have never had an existence without modern anæsthetics. The experimental work required in these departments could not have been done without their use.

Most of these operative procedures are also absolutely impracticable without the same. The most brilliant progress in surgery the world has ever known has been made since the discovery of modern anæsthetics. This wonderful progress has been so marked as to attract the attention of the laity. Says Dr. W. W. Keen: "This progress is due chiefly to two things—the introduction of antiseptic methods, and to what we have learned from laboratory work and experiments on animals."

It therefore appears that, at the beginning of this century, only two things were required to bring surgery to the highest possible standard. An anæsthetic was needed that the necessary experimental studies might be made on animals; furthermore, that all surgical operations might be carefully and properly performed; while the antiseptic method of wound treatment was required for the banishment of all septic complications. It must be now universally admitted by every careful student of surgery that the introduction of the aseptic method of wound treatment marks an era in surgical progress only second to that dependent on the use of anæsthesia.

The world is indebted to Sir Joseph Lister, of London, who primarily perfected and popularized this method of wound treatment. He has been far more successful than the majority of innovators, since he has lived to see the value of his labors universally acknowledged by the principal surgeons in every part of the world. The marvelous feats performed in brain surgery, relating to the removal of tumors alone, is thus stated by Dr. Keen: "Now, there have been twenty tumors removed from the brain, of which seventeen have been removed from the cerebrum, with thirteen recoveries, and three from the more dangerous part of the cerebellum, all of which proved fatal. Until this recent innovation every case of tumor of the brain was absolutely hopeless."

These successes in brain surgery have been made possible principally by the experimental studies of Ferrier and Horsley, of England; Fritsch, Hertzig, and Goltz, of Germany. In another part of this paper we have mentioned the fact that the first ovariotomy was performed in 1809; but only thirty-five years ago the abdomen was really a closed cavity, and the entrance of the same was even then practically tabooed by every prudent surgeon. Accidental wounds of this cavity, with very few exceptions, terminated fatally. Dr. Keen, in speaking of the success of operative procedures on this cavity, says:* "Mr. Tait has completed

* Dr. Keen in *Harper's New Monthly Magazine*, October, 1889, pp. 703 *et seq.*

a second series of one thousand cases in which he opened the abdomen for the removal of tumors, for abscesses, for explorations, etc. In his first thousand cases only ninety-two patients died (9·2 per cent.), and in the second thousand only fifty-three died (5·3 per cent.).

"In ovariotomy alone the percentage fell from 8·1 in the first thousand to 3·3 in the second. Only a quarter of a century ago the mortality of ovariotomy was but little if at all under 50 per centum. . . .

"Spencer Wells, even with the far larger mortality of his earlier days, added twenty thousand years to human life as the net result of one thousand ovariotomies."

How changed the condition to-day in regard to this cavity, since not a single organ within it is any longer exempt from the work performed by the surgeon's knife! The uterus is now frequently successfully extirpated, gunshot and stab wounds of the intestines are sutured, etc. In this cavity American surgery has led the way, and to Americans surely belong the highest honors. The first case of abdominal section for traumatism was that of Dr. Walters, of Pittsburgh, Pa., for ruptured bladder, in 1862. The first case for gunshot wound of the intestine was that of Dr. R. A. Kinloch, of Charleston, S. C., in 1863. "The elder Gross long since led the way by his experiments on dogs, but we owe our present boldness and success chiefly to the experiments of Parkes, Bull, and Senn—all Americans—who have first shown in animals that it was safe and right, with antiseptic methods, to interfere actively for the health and healing of our patients."

In the department of gynæcology the highest honors ever won justly belong to Dr. J. Marion Sims, of New York, who finally succeeded, after many years of patient and industrious experimentation, in discovering a method by which he was enabled to certainly and effectually cure both vesico-vaginal and recto-vaginal fistulæ. Dr. George J. Fisher says of this great surgeon, who has certainly immortalized his name by his labors,* that "every now and then the world is amazed by the appearance of a genius who, in a few short years, does the work which all previous centuries had failed to do, teaches his lessons well, becomes immortal, and flits away. It is impossible to speak too highly of such a one who has just departed. Gynæcology scarcely had an existence previous to the commencement of J. Marion Sims's brilliant and successful operations for vesico-vaginal fistulæ. There is nothing in the whole domain of surgery at all comparable with this man's contributions to gynæcology. He taught how to effect the absolute and permanent cure of the most distressing and loathsome condition of woman which it is possible to imagine, resulting from the injuries and lacerations incident to difficult childbirth, a condition which the most skillful surgeons had up to that time utterly failed even to ameliorate. Frankly and freely, and without remuneration, to go forth to all the principal civilized nations of the earth, personally and unreservedly to teach the surgeons of the world all his methods, and to establish model hospitals for the benefit of multitudes of afflicted women, furnished an example of broad and generous humanity, and of unselfishness, to which the world had been before a stranger.

"Dr. Sims well merited all the appreciation, admiration, and glory which were rather tardily bestowed upon him. In future the civilized world will never cease to express its unlimited gratitude for his eminent services, and this will be repeated age after age as long as the primæval curse shall rest upon woman, and until she shall enter upon a millennium when sickness and disease shall be no more."

The present high standard of orthopædic surgery is due very largely to the efforts of an American surgeon, who, by his energy and mechanical skill, brought about a reformation in the treatment of these morbid conditions which has yielded the most satisfactory results in these cases. Professor Lewis A. Sayre, of New York, has won the highest laurels in this department of surgery, and may be properly regarded as the father of the present method of treatment of these cases. Dr. Bigelow, of Boston, Mass., has introduced and popularized a method of rapid lithotrity which has attracted much attention in professional circles, and been accepted as a marked improvement over the other mode of treatment.

The limits of this paper forbid that more time should be occupied in bringing forward the grand achievements of a noble profession. Let the aspirant for honors in this field remember that he who enters here, with the full determination of gaining honest laurels, must possess all the qualities of mind and body which would secure fame for him on the field of battle. The battle for honest fame is always a desperate struggle; many must fall by the wayside and be carried to the rear fainting and disappointed; some of these will so far recover that they may, after a while, return to the front to again renew their struggle, while others will be buried in unknown graves, unhonored and unwept.

The moment an aspirant enters a gladiatorial contest for fame he will hear the jeers of the populace, will be confronted by his foe, and will require the courage of a lion. Having already gained the victory, he will then find that his *confrères*, still fearing that a full acknowledgment of the dearly earned laurels, so recently won, may possibly have an injurious influence on their own reputation or business, contrive that to the hero only fair words and no substantial aid will be given. Dr. J. Marion Sims must have fully realized the force of all these facts when he came to New York, after having patiently studied gynæcology for years, when he demonstrated to Dr. Valentine Mott and others the methods by which he was enabled to heal vesico-vaginal fistulæ, and performed several operations in their presence which resulted in perfect cures, *since still they would not consent* to join with him in the establishment of a female hospital where he could have an opportunity of carrying forward his humane work. Poor Sims, in this moment of despondency, came in contact with a true friend, a newspaper man, who said to him, "*You shall succeed; your mission is a noble one, and you are worthy of success.*" The good Samaritan called a public meeting, which was attended by the best people in New York city, except physicians, who were especially conspicuous by their absence. The charitable designs of Sims were fairly presented, as well as

* *International Encyclopædia of Surgery*, vol. vi, p. 1201.

the great value of his recent discoveries to suffering humanity. This meeting resolved that Dr. Sims should have an opportunity to go forward with his noble work. The following morning the newspapers gave a full report of the doings at this gathering. The effect of this report on the distinguished surgeons was magical. They promptly drove to Dr. Sims's residence and congratulated him on his prospects, magnified the value of his discoveries, and proffered their assistance. *His laurels were won and his worth was duly acknowledged.* These points have been brought forward to illustrate the difficulties with which all great advances have to contend. Dr. Sims's trials and difficulties were no greater than those which have obstructed progress in all former times. The following question now presents itself for our consideration: Is fame worth the effort? We all recognize the fact that Dr. Sims has erected over his bones an imperishable monument; but this is *no reward* for the great effort which he put forth. However, there is another and far nobler result which he has accomplished. His labors will, for ages yet to come, prevent thousands from suffering untold agony.

In this light we behold him as the benefactor of the whole human race, entitled to their sincere homage, and one who should be glorified on earth. Labor in such a field is the grandest in which any human being can ever engage, while death in such a cause raises a man almost to the level of the gods. The old pagan civilization fully recognized this right, and he who became distinguished as a mighty healer of the sick was henceforth classed among the gods. Let us so far imitate this worthy example as to dedicate the temples erected for the healing of the sick and wounded to the men in our own noble profession who have immortalized their names on earth by their untiring efforts in behalf of suffering humanity. Let honor be given to whom honor is due. Then we shall see hospitals bearing the names Paré, Hunter, Morton, Simpson, McDowell, Lister, Sims, Gross, etc., instead of those of "faith-curing" monks and questionable saints, who lived in the dark ages when ignorance and superstition won all the prizes.

Original Communications.

THE AFTER-TREATMENT OF OBSTETRIC CASES.*

By WILLIAM B. WOOD, M. D.

From series of observations and tests which need not now be detailed I some years ago became convinced that the number of cases of confinement in which the cervix was torn was really much greater than any published average. I now believe that slight lacerations at least occur in every confinement. The cases upon which this conclusion is based include many that have been handled by the best obstetricians in New York, than whom, as a class, there are no better in the world.

* Read before the Section in Practice of Medicine of the New York Academy of Medicine, May 20, 1890.

The reason why many of these lacerations are unnoticed and unrecorded is because nature so rapidly repairs such damage that the lesser tears are already healed before the usual time for making an examination. Even more considerable lacerations often escape detection until serious secondary symptoms undermine the woman's general health and send her to the specialist to undergo heroic methods of repair.

For five years I have worked upon the theory that if the minor lacerations, which are to be found immediately after labor, are so kindly and rapidly healed, the more serious ones would also heal if the wounds could be kept long enough in conditions favorable to such repair.

Under a proper system of treatment not only will there be healing of fresh lacerations, but long-standing and troublesome tears may in a later confinement be encouraged to heal, and will, as effectively as if by an operation, disappear. The history of several of the many cases in which such late union has been successfully accomplished will be published later. I need now say only that, under the system of treatment pursued, not only in no case has a fresh laceration remained ununited, but lacerations that were extensive and of long standing have, after being stretched and freshened by a second confinement, come together in such healthy union that it would require an expert to detect that the woman had ever been pregnant.

If I am right in my conclusion as to the great number of cases in which lacerations occur, then the importance of any method that shall obviate permanent injury is manifest. That lacerations are more frequent than was once thought possible is now accepted by all authorities in gynæcological science. The physician who declares that no patient of his ever had a laceration, and he who proclaims his thousand women confined without a torn uterus, now receives only ridicule for his boasting, while the rest of the profession struggle to heal the rents in the uteri that were so loudly declared unlacerated.

The old-fashioned argument was that nature never would make such bungling work of a normal function, and therefore if the uterus was torn it must necessarily be the fault of the accoucheur. The case of the savage was also frequently brought into the question, and her easy delivery given as an evidence of what nature could do if there were no medical interference. Now, however, we know that the best skill can not prevent, but only moderate and control, the extent of lacerations, and that the labor of the savage, who steps aside from the line of march, drops her infant, and then walks on with it in her arms, has little more relation to the labor of civilized woman than the dropping of a calf or colt. The fact that is pertinent to the present question, and which is quite sufficient to explain why civilized have more difficult labor than savage women, is the well-known law in comparative anatomy that as races advance into higher development the cranium increases in size, while the pelvic frame as steadily diminishes. With increased circumference of the infant's head and diminished aperture of the mother's pelvis difficult labor is the penalty race and individual pay for their civilization.

Any consideration of the final outcome of this state of

things, or discussion of its remedy, is apart from the branch of the subject which we now have to consider; but the fact remains as an indisputable law in development, and entails *present* injuries to child-bearing women which demand *present* remedies that shall make severe surgical operations unnecessary, or at least infrequent, and shall lessen the sum of accumulated evils that afflict so large a proportion of the women who have been mothers.

Outside of lacerated cervix, no other one cause of discomfort consequent upon confinement is so universal and obstinate as arrested involution. Both these evils can be made to yield to the one system of treatment which I have adopted as a regular routine in all puerperal cases, and which five years of trial have convinced me will give brilliant results in the hands of any careful practitioner.

Under favorable and in uncomplicated conditions the uterus returns to its normal size and weight not sooner than in from six to ten weeks. Dr. Lusk says that at the end of the second week after confinement the average weight is three quarters of a pound, the length is five inches, and the walls are barely half an inch in thickness. The vagina is still much relaxed, as it requires three or four weeks for it to regain its normal dimensions.

The increased size and weight of the uterus, the relaxed condition of the uterine supports, the flaccidity, inelasticity, and engorgement of the deeper portions of the vagina and the pelvis, according to the best authority, exist in the majority of cases from six to twelve weeks, and even longer in women in whom the intellectual powers have been developed at the expense of the physical.

Yet it is in the second week, while the uterus is of five or six times its usual weight, with the deeper lacerations still unhealed, that most women assume the upright position and resume their active occupations. As a result, the uterus drops low down or tips out of its normal position, thus by pressure retarding the return circulation and putting the relaxed uterine appendages upon a dangerous stretch. The unhealed surfaces at the mouth of the uterus are forced apart by the downward traction, and the ununited edges of the laceration heal wide apart, leaving the woman with a permanent tear, which a greater degree of caution could have prevented. In this condition, with uterus permanently over-heavy and over-large, lying crowded low down or displaced, the tubes swollen and sensitive, sagging down behind the uterus, between it and the rectum, the woman can hope for neither good health nor average usefulness. The evils that follow from this condition, which is classic, are universally recognized by the profession. They have been most vividly and accurately summed up by Dr. Emmet in his work on *Gynæcology*. I believe they can be avoided by increased care and prolonged treatment during and after the puerperal period.

The patient should before confinement be educated up to a conception of the importance of submitting implicitly to the directions given. Even in normal conditions of the uterus the supports are too frequently inadequate to hold that organ in place. The human race has not yet, in the process of evolution, perfectly adapted itself to the upright attitude; only in the genu-pectoral or quadruped position does the human uterus have perfect support; when, therefore, the puerperal condition overtaxes these already inadequate supports, they almost invariably fail to perform their natural function.

The first requisite, therefore, of a successful treatment is to keep the uterus well up until involution and healing are complete; otherwise both are arrested

After confinement the mother should be kept in bed for four weeks. The recumbent position should be strictly maintained for from fourteen to twenty-one days, the patient being allowed to lie upon the back, face, or side, but never to assume the upright posture. At the end of twenty-one days an examination should be made with the patient in either the Sims or genu-pectoral position, great care being taken not to stretch the perinæum.

After twenty-one days, hot injections, given after Dr. Emmet's method, may often be used to advantage, but should not, in my opinion, be employed where there have been extensive lacerations which are still unhealed, as the hot water, given in long injections, renders more difficult the union of the surfaces, which will sometimes unite, provided the recumbent position be so long maintained, as late as the fifth week. If at the end of the fourth week the condition of the cervix is satisfactory, the patient may safely be allowed to get up; but never on any condition without first having the still over-heavy uterus supported by well-adjusted pads. The patient is placed in the genu-pectoral position, prepared pads of surgeon's wool dipped in boroglycerin are packed in under and behind the uterus to hold it in normal position and to relieve the relaxed appendages of the extra weight. In from five to eight weeks after confinement the uterus will, in favorable cases, with this assistance, have returned to its normal condition, and will remain in natural position without artificial support.

The physician should, however, examine the patient once a month for a year after confinement, to assure himself that no displacement has been brought about by accidental causes. Many maintain that women will not be at so much trouble, and will not afford the physician an opportunity to follow cases such a length of time; in hospital and charity work they usually will not and can not, but the class of women met with in private practice will, if their physician educates them to a realization of the importance of such caution in its bearing upon their whole future state of health. In my experience there are few women who will not cheerfully submit to any course of treatment that obviates the necessity for an operation.

Let a woman who has serious laceration of the cervix and who contemplates submission to the surgeon's knife come to learn that there is a possible and simpler remedy after and through a second confinement, the success of which remedy depends upon her strict obedience to directions, and there is small danger of any rebellion on her part, even though you prolong the four weeks in bed to eight, as is occasionally necessary. The greater part of a physician's duty is to educate his patients to an intelligent comprehension of and rational co-operation in his methods of treatment. The day for dogmatic dicta is past.

The favorable reflex influence that nursing has upon the

pelvic organs is an important element in stimulating them to return to normal conditions. When, however, lactation becomes a drain upon the general vitality of the mother, this unfavorable condition more than counterbalances the favorable stimulation which the uterus thus receives. There is a large class of women with highly developed nervous systems who begin to show the drain of lactation as early as from the third to the twelfth week after confinement. In such cases the whole surplus vital energy is absorbed by the lactative function and the all-important reparative process in the uterus and its appendages is checked, and, unless the nursing is promptly discontinued, is permanently arrested.

With the improved methods of sterilized feeding there is little risk to the child in weaning it from the breast, while there is, in certain conditions, great risk to the mother in continuing to nurse the babe.

When all is said about confinement, its complications and evil sequences, the increase of the difficulties caused by advancing civilization and the artificiality of town life are really more than counterbalanced by the remarkable improvement in gynæcology which has been made during the last decade; so that the death-rate both for women in childbirth and for new-born children is actually decreasing rather than increasing.

Antisepsis has eliminated the most dreaded elements of childbirth; surgical skill is now able successfully to repair, immediately after the termination of labor, injuries to the vaginal outlet, and it only requires that we should adopt a system of after-treatment that will prevent arrested involution and permanently lacerated cervix to do away with all the most common undesirable results of confinement, and remove to a great degree the dread of childbed, which with some otherwise reasonable women amounts to a mania.

22 East Forty-first Street.

TWO CASES SHOWING THE TREATMENT OF LEPROSY:

(1) BY EXCISION OF TUBERCLES;
(2) WITH OINTMENT OF RED IODIDE OF MERCURY.

By BEAVEN RAKE, M. D. Lond.,
MEDICAL SUPERINTENDENT OF THE TRINIDAD LEPER ASYLUM.

The Treatment of Early Leprosy by Excision of Tubercles.

The treatment of tubercular leprosy by excision has been somewhat fully discussed in the *Asylum Report* for 1885, and also in an article in the *British Medical Journal* (June 9, 1888, p. 1214). I do not propose, therefore, to add very much here to what I have already written, but simply to describe a very early case in which I had the opportunity of trying excision.

Ernest Berrington, negro, aged eight, was admitted to the asylum on June 3, 1889. I had previously seen him as a private patient, and urged his coming in for operative treatment.

His condition on admission was described as follows: On the left cheek is an isolated circular mass of tubercles about an inch and a quarter in diameter. Round it are small tubercles of about the size of peas. On the nose and right cheek are several solitary tubercles the size of small shot.

There is a solitary tubercle of the size of a pea above the right elbow. The fingers are rather swollen.

The skin over the shins is tense and copper-colored. There are several small tubercles on the left calf and above the left knee. Soles are anæsthetic; femoral glands on both sides and axillary on right side are enlarged. The disease began with an eruption of tubercles on the left cheek about eighteen months ago.

June 10th.—Was given chloroform, and with a very sharp knife the mass of tubercles was shaved off the left cheek. Then fuming nitric acid was rubbed in, and afterward tannin applied. The small isolated tubercles on both cheeks, forehead, chin, both legs, and above right elbow were similarly treated.

12th.—Sites of isolated tubercles covered with scabs which have sunk in. On left cheek is a large scab and some discharge. The sores are being dressed with pure creolin. Patient was ordered liquor hydrarg. perchlor., ℥j; inf. quassiæ, ad ℥j, t. i. d.

July 10th.—Face nearly healed, but fresh tubercle has appeared under right eye and also under left eye.

From this date the tubercles have gradually increased both in the sites of excision and elsewhere. On two occasions they have been inoculated with leprous cultures, with the result of setting up a certain amount of ulceration in the tubercles, not materially checking their progress. At the present time the mass of tubercles below the left eye is ulcerating, and the tubercle above the right elbow is scabbed over, but still increasing.

I am always on the lookout for early cases of leprosy, for it is to them that we must look for any success in treatment. I hoped that free removal with a sharp knife, followed by the thorough rubbing in of fuming nitric acid and the use of large doses of mercury internally, might arrest the disease. Leloir has taken up the same idea that leprosy may be a purely local growth at first, and so complete destruction of tubercles may prevent a general invasion of the economy. In favor of this I may cite my failure ever to find bacilli in the blood of lepers at any stage of the disease, or to cultivate them from leprous blood. The treatment by excision will certainly be worth trying again, in a still earlier subject if possible.

The Treatment of Tuberculated Leprosy by Red-Iodide-of-Mercury Ointment.

Raymond H., negro, aged eight, was admitted to the asylum on September 16, 1889. He had been suffering from tuberculated leprosy for some years.

His state on admission was as follows: Numerous tubercles of the size of small shot on forehead, cheeks, chin, and ears. Few small pale-brown patches on back.

General swelling of forearms, hands, and fingers, also of legs, feet, and toes. Pale-brown, raised, shining masses near elbows and knees. Sensation perhaps slightly lessened in fingers and toes, but this appears to be due to thickening of tissues. Cervical, axillary, and femoral glands enlarged.

September 18th.—Ordered ung. hydrarg. iodid. rubr—one application to be made to the whole body and extremities.

25th.—Desquamating freely after one application. Number of separate tubercles on face and ears seems less. To have another application to-night.

27th.—Face swollen, puffy below eyes. Not salivated.

October 2d.—Not much change in tubercles of face since last time. Repeat ointment to-night.

16th.—Small tubercles of face about the same, also swelling of extremities. Repeat ointment to-night.

23d.—Skin peeling from face and neck. Tubercles about the same. Hands and feet swollen. Not much evidence of ointment on extremities.

28th.—Was rubbed with ointment again last night. Face a little swollen, but less effect than at first.

November 8th.—Tubercles increasing on ears, cheek, forehead, and chin. Repeat ointment to-night.

11th.—Blisters on back from ointment. Face swollen. Some salivation. Tubercles have increased on face. Large lumps over angles of jaws.

As in this case the disease took the form of a general infiltration of the extremities, with a few small tubercles on the face, it was thought that a strong germicide ointment, like red iodide of mercury, might succeed in killing the bacilli and reducing the infiltration and tubercles. At first there seemed to be slight improvement, but after a few applications the ointment lost its caustic effect on the skin, though in the end salivation was set up and the remedy discontinued. Tuberculation is now progressing in the patient.

TRAUMATIC ANEURYSM OF THE INTERNAL MAXILLARY ARTERY.

COMPRESSION; RECOVERY.

By WILLIAM C. KRAUSS, B. S., M. D.,

LECTURER ON PATHOLOGY, AND ASSISTANT TO THE CHAIR OF CLINICAL MEDICINE, NIAGARA UNIVERSITY MEDICAL COLLEGE, BUFFALO, N. Y.

J. McH., aged thirty-four years and one month; single; weight, one hundred and seventy pounds; height, five feet seven inches; occupation, painter; constitution, strong, robust; antecedents—parents both living and healthy, offering no hereditary taint of any kind; no history of syphilis, tuberculosis, alcoholism, or rheumatism.

Early History.—No infantile diseases. Patient has always been a healthy man with the exception of an attack of lead colic which occurred three years ago. Was obliged to suspend work for three months. No palsy or cerebral symptoms intervened, and the attack passed off without any apparent sequels.

Present History.—In the afternoon of August 23, 1889, as the patient was at work on a staging sixteen feet high, it suddenly gave way and he was precipitated to the ground. His companions say he fell backward, striking upon the left side of his head. He was picked up unconscious, having received several contusions, the largest being over the left temporal fossa; no fractures or dislocations were recognizable. After a lapse of several hours he regained consciousness, and complained of nausea, vertigo, and syncope, which continued for some time. He noticed no peculiar sensation about the head except a dull, heavy ache, and some pain over the left temporal fossa, which was swollen and quite sensitive to touch. He retired early that evening, his sleep being much disturbed owing to pain and excitement. The following morning he was awakened from a short sleep by a hissing noise which seemed to come from the pillow, and which the patient thought was produced by a snake. His search through the pillow and bedding revealing nothing, he concluded that the noise was in his head, and more especially in the ears. Being unable to stop the hissing sound by plugging the ears, he consulted a physician, who applied blisters behind the ears and ordered aural douches.

The patient, experimenting upon himself, found that by several manipulations he was able to control the sound temporarily: by holding the breath for a time, the bruit would grow fainter and disappear entirely, but on respiring would reappear; pressure over the left temporal fossa and on the neck (carotid) would intercept the noise; biting the teeth firmly together would also stop the sound for the time being.

The sound is described as a hissing, at times squeaking noise, continuous by night and day. Exercise increases its intensity and rhythm; rest, on the other hand, diminishes the same. At night it seems to grow more impetuous, owing no doubt to the stillness of the surroundings. No other subjective symptoms are noticed except a dull, heavy feeling on the left side of the head, and at times a slight vertigo.

The patient consulted me for the first time August 30, 1889, and gave in substance the foregoing history. On subjecting him to a careful examination, the following objective symptoms were obtained: There is present a slight swelling at the junction of the malar and zygomatic process of the frontal bone, with some discoloration. An impulse is perceptible under the finger, diffused and feeble, simultaneous with the radial pulse. The anterior and posterior temporal arteries can be distinctly traced from their points of origin to some distance mesad, and show no irregularity. Percussion of the cranium gives a negative result, save a dull, heavy pain over the left temporal fossa and malar bone.

Auscultation.—A stethoscope applied over this region elicits an interrupted, sharp, hissing bruit, synchronous with the apex beat, having its point of greatest intensity about an inch dorsad of the external canthus of the left orbit. The bruit is less intense over the temporal fossa, and less distinct over the left upper side of the head. On the right side the bruit is also audible, but much less distinctly.

Digital pressure over the external carotid artery at the inferior posterior angle of the inferior maxillary bone produces a complete and sudden cessation of the bruit; pressure over the common temporal artery over the malar bone does not alter the bruit in character or intensity. The stethoscope, when applied with some force over the left temporal fossa, intercepts the bruit. An examination of the ears shows congestion of the membrana tympani on the left side; examination of the eyes and mouth gives a negative result.

The diagnosis, based upon the objective symptoms, is that of a deep-seated aneurysm situated in the left temporal fossa, which by exclusion is shown to be of the internal maxillary artery or one of its branches. The patient was presented before the Buffalo Pathological Society, November, 1889 (*Buffalo Med. and Surg. Journal*, December, 1889, p. 292), and the diagnosis confirmed.

The treatment of the case has been with ergot, iodides, and light cathartics. The bruit seeming to grow more intense, it was proposed, if pressure proved of no avail, to resort to a surgical operation—that of tying the left external carotid artery. The patient being averse to operative procedure, a U-shaped spring with pads at both ends was applied to the head, so that one pad rested in the left temporal fossa. This spring was applied every night for a period of ten weeks, and resulted in the complete cessation of the bruit (February 6, 1890) and disappearance of all subjective and objective symptoms. The patient is now capable of doing all kinds of work coming within his domain without the least disturbance or annoyance, and considers himself perfectly cured.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by Frank P Foster, M. D.

NEW YORK, SATURDAY, AUGUST 2, 1890.

A SENSELESS PANIC OVER LEPROSY.

From this week's report of contagious diseases in New York it will be seen that a case of anæsthetic leprosy has been reported. The patient is a young man, aged twenty years, a native of Central America, who has been attending school in this country for more than a year. The symptoms of the disease did not appear until after an attack of influenza during the past winter, and at first the true character of the complaint was not recognized, but when a definite diagnosis was made and the case reported to the board of health the patient was forcibly removed, by order of the board, to North Brothers Island.

We must deprecate this action of the board, that seems based upon the fear of leprosy that probably most persons entertain as a result of biblical reading. Why should the treatment indicated in Leviticus be followed in this disease, while many of the other sanitary injunctions of the Old Testament are properly ignored? Should our treatment of such cases be traditional or scientific? True, this action of the board has two precedents in this country; one, the instance in which the Philadelphia Board of Health exercised its authority in forcibly confining two lepers in 1888, and the other the one in which in St. Louis an unfortunate leper was taken from his friends by order of the local board of health and confined in a lazaretto until he died. In the latter case a slight effort was made to secure the release of the patient by habeas-corpus proceedings; and the tenor of the popular impression regarding the disease can not be better illustrated than by the fact that there was a stampede from the court-room, even the wearer of the judicial ermine sharing in the fright, when it was learned that the leper in person had been brought into court. Had a consumptive been brought into the room it is needless to say that no such alarm would have been created; and yet, conceding the most ultra virulence to leprosy and the justifiability of the most extreme views held by lepraphobists, it can not be held that the disease is as contagious as tuberculosis, or that it causes even a small percentage of as many deaths as the latter.

The sanitary regulation authorizing inspectors of the Marine Hospital Service to exclude leprous immigrants is an excellent one, because such persons will probably become public charges. Nevertheless, even with this regulation, we doubt if an American citizen could either be legally excluded from the country or be confined as a virtual prisoner in a lazaretto, because he had unfortunately acquired leprosy during a residence in certain foreign countries. At a recent meeting, in June last, of the representatives of the State and local boards of health, at Nashville, an effort was made to obtain the adoption by that body of regulations requiring the isolation of lepers in the United States. The evidence that supported the theory of the acute contagiousness of leprosy in this country was considered so inconclusive that this association of experts declined to adopt the regulations advocated by one or two radical members.

In Minnesota, South Carolina, Florida, Louisiana, and California there are cases of leprosy. In the last-named State the patients are principally Chinese, and, on account of the susceptibility of that race to the mild contagion of the disease, lepers are isolated. But in none of the other States named has any attempt been made to isolate the patients; yet there is no evidence that the disease has increased in any of them during the past century, and there is but a single authentic record of the disease being acquired by association in this country. This latter case was in a Roman Catholic priest attending leprous patients in Charity Hospital, New Orleans; it was supposed that he acquired it by the custom of inunction of the dying. He was an American Father Damien who received no honors in his own country.

That the *Bacillus lepræ* can cause the disease by inoculation is uncertain, for in the case of a condemned criminal inoculated in 1884, in whom the leprous bacilli were found in the cicatrix in 1885, he did not show signs of general infection until 1889. Again, consider for one moment the many years that Father Damien was exposed to the disease before he acquired it. Besides the micro-organism, certain factors of climate, environment, and food seem requisite; possibly, besides, what Jonathan Hutchinson has designated as "some very special kind of poison of rare occurrence taken in connection with food." Certainly climate exercises a potent influence in keeping the disease in abeyance, as has been proved in cases of Englishmen that have acquired leprosy in colonial possessions and have lived in fairly good health on returning to England.

To deprive an individual of his liberty is a very serious matter, and, in view of the fact that contagious diseases of far greater danger to public health than leprosy are treated at the domicile, there seems to be no good reason for such arbitrary, though well intended, action as that taken by the board of health. If experience with the West Indians that are the lepers in Florida, the Acadian descendants that constitute the Louisiana lepers, or the Norwegian lepers in Minnesota, justified a belief in a danger to this community in permitting this patient to reside with his family, the case would be different. But to cite the illustration of a primitive people like the Sandwich Islanders, that have been successively decimated by contagious diseases, and in every way shown their inability to resist diseases less noxious to the white race, or of the unsanitarily situated natives of India, as reasons for our better-circumstanced population fearing the spread of a disease that occasionally presents itself among us, is to ignore the therapeutic resources of our profession—for cures of lepers have been reported—and to place as naught the hygienic advantages of civilized communities.

THE HARLEM ABORTION CASE.

A case of criminal abortion that has lately come to light in Harlem presents more than the usual array of horrors; fortunately, by that very fact it is likely to prove useful among the community. The public prosecutor expects to prove that a girl obtained, or her lover obtained for her, the ghastly services of a physician to assist her in avoiding maternity, and that she died in consequence of his interference. The physician is a licensed practitioner, but his name does not appear in the *Medical Register*, and it is stated that he has previously been under what the police considered well-grounded suspicion of his having been concerned in the criminal production of abortion. The special features of horror in the case are said to be that the girl was taken to a squalid tenement, where she had nobody to nurse her but a repulsive woman employed by the doctor; that, after she had died, her remains, wrapped only in an old quilt, were carried by the doctor himself, at dead of night, to a complaisant undertaker's shop; that this undertaker obtained a burial permit on the doctor's certificate that the girl's death had resulted from rheumatism of the heart, the name assigned to the deceased being fictitious; that she was buried secretly, the fact of her death being withheld from her relatives; that the story of the wrong that had been done her came to light only after some very clever detective work based on a conversation casually overheard by an officer on an elevated railway train; and, finally, that the poor creature's dead body was exhumed, subjected to a medico-legal examination, and held until it had advanced so far in decomposition as to be a sight that the coroner's jury found sickening.

This is indeed an atrocious case. That the public appreciates its atrociousness is shown by threats to lynch the old doctor. It is idle to hope that contemplation of the case will have any considerable deterrent influence on the monsters who make a practice of criminal abortion; they will simply chuckle and congratulate themselves that they are not such blunderers as the doctor in this case has shown himself to be. But the lesson can not be wholly lost to the community. We have no expectation of seeing the public conscience perceive the fact that criminal abortion is always murder, whether the woman perishes or survives; but what we do expect is an increase in the number of those who appreciate the terrible risk inseparable from recourse to induced abortion, and consequently will use every means to avoid the crime for fear of the consequences. This, of course, can not be accounted a gain to public morality, but its natural results must, nevertheless, conduce to the public safety. What we should like to see established as an adjuvant is some provision whereby indiscreet women who find themselves pregnant out of wedlock may be assured of decent support and secrecy until they are relieved of their embarrassment by the birth of a full-time child and recovery from the disabilities of the lying in period. We believe that institutions for this purpose, properly managed, would do more to break up the horrid practice of abortion than all the eloquence that has ever been brought to bear in picturing its immorality.

MINOR PARAGRAPHS.

INTUSSUSCEPTION TREATED WITH THE AID OF BARNES'S BAG.

Rivington, of London (*British Medical Journal*), has employed Barnes's bag in the treatment of two cases of intussusception. The first patient was a man presenting a constriction of the rectum and an intussusception of limited extent which could be felt from the rectum. Upon the introduction and inflation of the bag the tumor readily receded and soon disappeared, not to return. The second patient was a child, seven months old, with a history of vomiting and passages of liquid and blood for two weeks. The bowel was found to be prolapsed and the ileo-cæcal valve formed the apex of the invaginated portion. Partial reduction was easily effected, but all attempts at complete reduction by insufflation or the injection of fluid utterly failed. A Barnes's bag was introduced simply for the purpose of retaining the mass. It was removed twice a day to allow of the escape of liquid passages. At the end of two days, without any other attempt at reduction, the intussusception had entirely disappeared. Whether peristaltic action exerted fruitlessly for the expulsion of the bag had assisted in the reduction, or whether it had been accomplished by the collection of gas above the bag, is uncertain. The action of the bag was evidently quite different in the two cases. It would seem to be a valuable adjunct to other methods of treatment in intussusceptions that readily recur on replacement or do not disappear entirely under the use of injections of air or liquid.

ARISTOL IN OZÆNA.

According to the *Lancet*, Dr. Löwenstein strongly recommends the employment of aristol—iodide of thymol—in ozæna. It is said that the fœtor ceases and the ulcerations heal, with consequent disappearance of the scabby crusts. It is given pure in insufflations, and is also used as a collodion (aristol, 1 part; flexible collodion, 10 parts) applied to the ulcerations. It should be kept in dark glass bottles, because it is decomposed by light. Its very slight odor makes it a most desirable substitute for iodoform.

METHYLENE BLUE AS AN ANALGESIC.

In methylene blue that is free from chloride of zinc or other impurity, Professor Ehrlich and Dr. Lippman, says the *Lancet*, have found a safe analgesic that is cheaper than antipyrine and can be administered hypodermically without causing pain. It was given subcutaneously in grain doses; internally from a grain and a half to four grains were given, though fifteen grains a day produced no toxic symptom.

SALOL IN CHOLERA.

In the *Indian Medical Gazette* for September, 1889, Surgeon-Major C. F. Nicholson reported a number of cases of cholera successfully treated with salol. In the May number of the same journal, of this year, Dr. Hehir reports eleven cases of cholera treated with salol, all of which ended in recovery; while among seventy-seven cases of that disease treated with bichloride of mercury, thirty-nine—or 44·7 per cent.—were fatal. Löwenthal's investigations of the germicidal properties of salol on the comma bacillus suggested the practical application of that drug. It was administered every two hours, in ten-grain doses, with fifteen minims of spirit of chloroform. The severe symptoms gradually disappeared, the exosmotic process in the intestinal canal ceased, and the patients retained fluids that were

given. There was a shortening of the period of convalescence, with absence of the symptoms of uræmia. In the same journal Surgeon J. Stevenson reports four cases of cholera treated with salol that ended fatally. In only two of the cases did any improvement follow its use. Of course, more extensive statistics are requisite before definite conclusions regarding the utility of the drug in cholera can be drawn.

THE FOUNTAINS OF NEW YORK.

The supply of water delivered in New York having become abundant for the time being, owing to the flow through the new aqueduct, it has been proposed to set the public fountains going. Some doubt has been expressed, however, as to whether there is yet a sufficient head of water to make them flow to their old-time height. Be this as it may, the new supply is soon to be turned off, according to the announcements made, and held back either altogether or in great part until the work of repairing defects in the new aqueduct is completed—probably for a number of weeks. This being the case, it would be well, we think, to forego the pleasure of seeing the fountains play until an adequate supply of water can be made permanent; then, by all means, let the fountains be put in action.

AN ABUSE OF THE AMBULANCE SYSTEM.

An odd story is told in the newspapers of one of the hospital ambulance wagons having been summoned three times to convey one man to the hospital, and of its having been sent promptly each time, although on the first occasion it had been ascertained that the case was not of a nature to render hospital treatment necessary. It is said that when the last call was answered the patient was put under arrest, instead of being taken to the hospital, and "sent up" on a charge of having committed a misdemeanor. It seems, therefore, that this course can be pursued in cases of persistent ambulance calls on trivial grounds, but it is hard, if the account is true, that this particular patient should have been the first to be punished, for his friends allege that it was they and not he who sent the calls.

THE PHONOGRAPH AS A DISSEMINATOR OF DISEASE.

It is reported that the Philadelphia Park Commissioners have ordered the disuse of the public phonographs heretofore in use in Fairmount Park, on account of the danger of their serving to disseminate disease. This danger is doubtless very slight, like that of injury to the ear, and probably neither danger is worth consideration if the instrument is kept reasonably clean and used properly; but its promiscuous use in a public park does not seem to admit of perfect security in this respect, and the announcement that the phonograph company intends to substitute a plate ear-piece for the penetrating one now in use, avowedly for the reason that there are persons who object to the present form, goes to show that the Philadelphia Commissioners are not the only people who entertain the idea of danger in the phonograph.

THE RETIREMENT OF PROFESSOR VON BRÜCKE.

Hofrath Ernst von Brücke, who for many years has been the professor of physiology in the University of Vienna, is reported as having given his farewell lecture recently, on reaching the age at which retirement is called for. A number of the other professors formed a part of the audience on the occasion, and, together with the students, cheered von Brücke as he entered the room.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending July 29, 1890:

DISEASES.	Week ending July 22.		Week ending July 29.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	24	7	34	8
Scarlet fever	43	7	28	6
Cerebro-spinal meningitis	1	0	5	4
Measles	215	10	156	8
Diphtheria	72	21	75	31
Varicella	7	0	3	0
Leprosy	0	0	1	0

The New York State Medical Association.—The eighth special meeting of the Fifth District Branch was held at Kingston on Tuesday, July 22d, under the presidency of Dr. William McCollom, of Brooklyn. The programme included A Practical Study of the Region of the Spine and Pathological Changes occasioned in it by Traumatisms, by Dr. T. H. Manley; A Strange Case, by Dr. J. G. Porteous; and A Case of Acute Purulent Pleurisy—Pleurotomy, followed by Rapid Recovery.

The Chicago Polyclinic.—Dr. G. Fütterer has been appointed professor of internal medicine, Dr. F. C. Hotz professor of ophthalmology, Dr. E. Fletcher Ingals professor of laryngology, Dr. Charles F. Stillman associate professor of orthopædic surgery, Dr. P. S. Hayes associate professor of electro-therapeutics, and Dr. J. M. Patton associate professor of medicine.

The Death of Dr. R. C. Word, a prominent Georgia practitioner, took place at Decatur on the 20th of July. The deceased had for many years been an associate editor of the *Southern Medical Record* and teacher of physiology in the Southern Medical College, of Atlanta.

Dr. Nicholas Senn's Surgical Bacteriology.—A French translation of this very valuable work, by Dr. A. Broca, has just been published.

Change of Address.—Dr. A. M. Phelps and Dr. W. O. Plimpton, to No. 40 West Thirty-fourth Street.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending July 26, 1890:*

Stone, L. H., Assistant Surgeon. Ordered to the U. S. Receiving-ship New Hampshire.

Uric, J. F., Assistant Surgeon. Detached from the U. S. Receiving-ship New Hampshire and ordered to the U. S. Receiving-ship Wabash.

Norton, Oliver D., Passed Assistant Surgeon. Granted leave of absence for the month of August.

Babin, H. J., Surgeon. Granted one month's leave of absence from July 23d.

Society Meetings for the Coming Week:

Tuesday, *August 5th:* Hampden, Mass., District Medical Society (Springfield).

Letters to the Editor.

THE WEST VIRGINIA STATE BOARD OF HEALTH.

Charleston, W. Va., *July 23, 1890.*

To the Editor of the New York Medical Journal:

Sir: The State Board of Health of West Virginia has just closed its annual session of 1890. A communication was presented from the State Board of Health of Illinois asking the co-operation of the State board of West Virginia to raise the standard of instruction in the medical colleges and to require a three-years' course.

In accordance with the reqnest, the following preamble and resolutions were presented:

"*Whereas*, The growing importance of the careful preparation of medical students for entering upon the responsible positions as physicians and surgeons, and as a means of protecting the citizens of West Virginia against charlatans, as well as encouraging and fostering the landable efforts of reputable medical schools and colleges to raise the standard of medical education; therefore,

"*Resolved*, That the board earnestly recommends that all medical schools and colleges require attendance upon three full courses of lectnres, besides satisfactory evidence of preparatory education, attested by diploma or certificate from a reputable college, academy, or high school, and a certificate from a regnlar physician as to a full course of professional study, as requisite for graduation."

It is mortifying to me to say the board did not carry out the sentiment of the resolutions, which were unanimously adopted. Out of four applicants, two passed. One of them to my certain knowledge has never seen a medical college, but professes to have received some instruction from a gentleman who passed the State board a few years ago. He has a country school teacher's education.

The other gentleman has attended one course of lectures, which is that much to his credit. The code of the State of West Virginia says: "The board shall take cognizance of the interests of the life and health of the inhabitants of the State," etc., for which a solemnized oath is required.

Now, I ask how in the name of the profession can the State board of West Virginia have at heart the welfare of the people after passing such ill-prepared men, because we all know how poorly prepared a man is after he has studied with his preceptor for one year and has attended his two full courses of lectnres, and the board is certainly aware of the same fact, because they earnestly recommend a three-years' course at a reputable medical college.

And we further know that a man is not capable of practicing medicine and surgery without first receiving clinical instructions at the bedside by professional teachers. Any man who is so fortunate as to pass the State board is entitled to all the privileges and immunities which are guaranteed to a regular graduate of medicine, and I venture to say that nine tenths of such manufactured physicians will know less as they grow older. I have not attempted in my remarks to criticise the board; I simply want to place them before the profession at large and let it delegate hereafter to them their professional standing.

F. S. Thomas, M. D.

NITRATE OF POTASSIUM IN INTERMITTENT FEVER.

Hillsboro, Ill., *July 22, 1890.*

To the Editor of the New York Medical Journal:

Sir: In the *Virginia Medical Monthly* for Febrnary, 1890, Dr. J. D. Hunter professes to have made the discovery that nitrate of potassinm will cure ague.

I called the attention of the profession to the antiperiodic property possessed by this drug in a paper published in the *St. Louis Medical and Surgical Journal* in 1859 or 1860, and again in the *Boston Medical and Surgical Journal* some time in '63, '4, or '5. I have lost my journals by fire, and therefore can not be exact as to date.

I was induced to make a trial of this remedy after being assured by an old "backwoods" hunter that a large dose of gunpowder (which he usually took in whisky), given at the inception of the cold stage, would almost always abort the paroxysm, and that, if there should be any fever, it would be very light. I found this to be trne, and at once attributed the cure to the potassium nitrate, and upon trial found I was correct.

When the price of quinine was high it was a most excellent substitute, bnt, as it lacks the tonic effect, the cinchona alkaloids, at present prices, are preferable.

Amos Sawyer, M. D.

Proceedings of Societies.

RICHMOND, VA., ACADEMY OF MEDICINE AND SURGERY.

Meeting of June 10, 1890.

The President, Dr. W. W. Parker, in the Chair.

(*Reported by Dr. J. W. Hewson, Richmond.*)

A Peculiar Case of Indigestion.—Dr. J. N. Upshur reported the history of a peculiar case occurring in a lady of fifty-four years very much "run down" from mental and physical overwork. The peculiar feature was a severe pain, spasmodic in character, occurring periodically about every ten days. Its seat was about the pylorus and downward and to the right along the edge of the ribs. When the speaker first saw her she had three of these attacks, at intervals of about twelve honrs. The first he had relieved in a few hours with morphine and atropine hypodermically, the two last with one fiftieth-grain doses of nitroglycerin, administering it twice for the second, and only once for the third attack. No eructation of gas and water followed the last of the three, as had been the case always before. The general treatment given was a light nutritious diet, attention to the bowels, and a tonic of phosphate of iron, quinine, and strychnine. She had no recurrence of the pain. Nitroglycerin had been suggested to the speaker's mind by the fact that the pain in its acuteness resembled the spasm of angina pectoris. He had much confidence in nitroglycerin for the relief of the œdema, dyspnœa, and cardiac distress of Bright's disease. He had tried it with much success for the temporary relief of aggravated sciatica. Though it was slower in action, its effects were more permanent than those of nitrite of amyl.

Meeting of June 24, 1890.

A Sequela of La Grippe.—The President reported the history of the case of a robust young man who had been afflicted with influenza a short time ago, this being accompanied by an inflammation and considerable swelling of the muscles of the neck, and this in turn being followed by a frightful eruption of vesicular character over the whole body, very much like chicken-pox. It was particularly marked upon the hips and inner side of the thighs, where it resembled and might have been mistaken for confluent small-pox. The eruption continued ten days or two weeks, leaving the extremities first and gradually. There was no fever, very slight constitutional disturbance of any kind, and no itching of consequence.

Singular Experience with Scarlet Fever and Measles.—Dr. W. B. Grey reported in reference to two children, aged respectively two and four years, affected with scarlatina, the older one of whom, just about the commencement of desquamation, developed the eruption of measles. In four or five days the younger did the same. Furthermore, said the speaker, about this time the father, an old man, took scarlet fever.

Hæmatoma Auris.—Dr. Charles M. Shields reported the history of a case occurring in a lawyer of about sixty years of age, and perfectly sound in mind (the trouble very rarely appearing except in the insane). About a month before the appearance of the growth the man had suddenly lost consciousness one day, and, in falling, had bruised the side of his face corresponding to the trouble. The speaker had enlarged an opening found upon the anterior wall of the canal, about half an inch from the external orifice. The cavity into which it led would hold about five or six drachms. The discharge was very offensive. A wash of peroxide of hydrogen was prescribed. From one Saturday night until the following evening the patient had five or six hæmorrhages, losing in all about twenty or thirty ounces of blood. The only resource for perfect control of the flow was packing the cavity with cotton saturated in Monsel's solution. The speaker thought the man would recover, but with a considerable scar.

Dr. M. D. Hoge reported the history of a case of a man who since an attack of *la grippe* had fallen into a state of melancholia almost amounting to insanity. He suffered excessively from nervousness and from an intense pain the head, the latter being treated successively with morphine, cocaine, and bromide of potassium. He still complained of great pain in his head, until one night he pounded himself over the head with a poker until he had peeled off a large piece of scalp and produced enormous hæmorrhage. He then felt better. Some time after, the speaker found a sequestrum of bone (a portion of the external table) in the wound, which he removed, and the part began to heal beautifully. The man was very much depressed all along, and believed himself going crazy. He complained of hearing voices. The speaker reasoned him out of that state and pronounced him now upon the road to recovery.

The President thought the hearing of voices a pretty sure sign of insanity.

Book Notices.

Asthma, considered specially in Relation to Nasal Disease. By E. Schmiegelow, M. D., Consulting Physician in Laryngology to the Municipal Hospital, and Director of the Otolaryngological Department in the Polyclinic at Copenhagen. London: H. K. Lewis, 1890. Pp. 90.

This essay contains an historical review of theories relating to asthma; due justice to Hack for calling attention to conditions that had passed unnoticed, together with criticisms of his exaggerated views; and conclusions based on experience and investigation that are truly interesting. The author considers asthma a bulbar neurosis, consisting of an excessive reflex irritability of the respiratory center. He thinks that this neurosis may result from depressive factors, such as childbirth, bleeding, continued fever, etc.; that when this disorder appears in apparently healthy individuals, without trace of other nervous phenomena, it is presumably caused by frequent and strong irritations conducted to the respiratory centers from the nasal fibers of the trigeminus, and to this cause may be added irritation of other and more remote nerves, such as the laryngeal and pulmonary branches of the pneumogastric, or of any sensitive nerve whatever; that the suppression of peripheral irritation alone—as in the treatment of nasal disease—or combined with general nerve tonic treatment, may prevent asthmatic attacks; and that nasal disorders may exist accidentally in asthmatic persons without having the slightest etiological relation to the attacks. An effort to find out what asthma really is, to place it where it really belongs, and to relegate it largely to the generous care of the neurologist, marks the trend of medical thought in reference to certain respiratory and cardiac affections. Dr. May's recent reports of cases cured by hypodermics of strychnine and atropine, and Dr. Schmiegelow's clinical observations, make the outlook of asthmatic sufferers more hopeful.

BOOKS AND PAMPHLETS RECEIVED.

Annual of the Universal Medical Sciences. A Yearly Report of the Progress of the General Sanitary Sciences throughout the World. Edited by Charles E. Sajous, M. D., Lecturer on Laryngology and Rhinology in Jefferson Medical College, Philadelphia, etc., and Seventy Associate Editors, assisted by over Two Hundred Corresponding Editors, Collaborators, and Correspondents. Illustrated with Chromo-lithographs, Engravings, and Maps. Vols. I, II, III, IV, and V. Philadelphia and London: F. A. Davis, 1890.

Leçons cliniques sur les maladies de l'appareil locomoteur (os, articulations, muscles). Par le Dr. Kirmisson, Professeur agrégé de la Faculté de médecine; chirurgien de l'Hôpital des enfants assistés, etc. Avec 40 figures dans le texte. Paris: G. Masson, 1890. Pp. viii–350. [Prix, 10fr.]

Les anesthésiques: physiologie et applications chirurgicales. Par A. Dastre, Professeur de physiologie à la Sorbonne. Paris: G. Masson, 1890. Pp. xi–306. [Prix, 5fr.]

Practical Sanitary and Economic Cooking adapted to Persons of Moderate and Small Means. By Mrs. Mary Hinman Abel. The Lomb Prize Essay. Published by the American Public Health Association, 1890. Pp. xi–190.

A Natural Method of Physical Training. Making Muscle and reducing Flesh without Dieting or Apparatus. By Edwin Checkley. Third Edition. Fully illustrated from Photographs taken especially for this Treatise. Brooklyn: William C. Bryant & Co., 1890. Pp. 4–7 to 152.

Protoplasm and Life. Two Biological Essays. By Charles F. Cox, M. A. New York: N. D. C. Hodges, 1890. Pp. 3 to 67.

Gunshot Wounds of the Abdomen. By Aug. Schachner, M. D., of Louisville. [Reprinted from the *Annals of Surgery.*]

The Creasote Treatment of Tuberculosis, with a Description of a New Inhaler, and Impure Creasote the Cause of Failure in the Treatment of Pulmonary Tuberculosis. By G. W. Daywalt, M. D., San Francisco, Cal. [Reprinted from the *Occidental Medical Times.*]

On Conical Stump after Amputation in Children, with Especial Reference to its Physiological Causes and Prognosis. By Charles A. Powers, M. D. [Reprinted from the *Medical Record.*]

Annual Report of the Board of Health of the Health Department of the City of New York, for the Year ending December 31, 1889.

Second Annual Report of the Health Department of the City of Mansfield, Ohio, for the Year commencing March 1, 1889, and ending February 28, 1890. By R. Harvey Reed, M. D., Health Officer.

State Board of Health. Report of Willis G. Tucker, M. D., Ph. D., Analyst of Drugs.

Dei doveri del medico verso la società. Lezione di chiusura al corso di clinica propedeutica e patologia speciale medica, fatta all' università di Perugia. Por Dott. Carlo Ruata. [Estratto dalla *Salute pubblica.*]

Reports on the Progress of Medicine.

PHYSIOLOGY.

By Louise G. Rabinovitch, M. D.,
Philadelphia.

On the Period of Muscular Contraction during which Heat begins to Discharge.—Of the known fact that voluntary or induced muscular contraction is accompanied by heat production, the period during the contraction that corresponds to the production of heat is not known.

M. Maurice Mendelsohn (*Comptes rend. de la soc. de biol.*, No. 27, 1889) experimented for several years with the view of determining this period. He found most satisfactory the use of Bernshein's differential rheotome that communicates to the muscle momentary excitations at rapid intervals and of equal duration; it enables also, during the intervals, to shut off the muscular thermo-electric current for an extremely short time.

He was enabled to estimate the interval between the moment of muscular excitation and the discharge of heat; it is given in figures from 0·005 to 0·006 of a second. This interval constituting the latent period of muscular heat production appears to be inferior to the duration of the period of muscular contraction, that amounts, according to Helmholtz, to 0·01, and according to M. Mendelsohn himself to from 0·007 to 0·008 of a second.

He concludes from this that the beginning of the production of heat in the muscle is going on already during the latent period of muscular contraction.

The fact seems of importance to the author from several standpoints. It shows, in the first place, that the production of heat in the muscle precedes the mechanical effect of the excitation. It proves, further, that the latent period of the muscular contraction is not at all a period of muscular inactivity, but that during this short lapse of time there is already, subsequent to the excitation, discharge of certain vital forces. The muscular contraction is then only an ultimate and final effect of certain micro-chemical processes (or electrical, assuming that the electro-negative variation of the muscle current precedes the muscle contraction) which are going on during the persistence of the latent muscular period, and whose first effect is to produce heat. The heat is being produced during the period of muscular contraction, and to a very slight extent, or not at all, during the period of relaxation.

On Some of the Effects of Cold on the Human Body.—M. Féré (*ibid.*) has studied the subject and obtained the following results:

1. Simple exposure of the naked body to the air at a temperature of from 18° to 20° C. suffices to induce within several minutes an augmentation of pressure in the radial artery, which may amount to from 200 to 300 grammes at the end of ten minutes. The increase takes place even when the pressure is as high as 800 to 900 grammes. This fact explains why sudden exposure to a low temperature is apt to lead to rupture of the blood-vessels that have been previously altered. The augmented pressure thus determined explains also the occurrence of epilepsy subsequent to exposure to cold. Among the physiological phenomena caused by exposure to cold the author mentions the occurrence of considerable supersecretion from the axillary sudorific glands; this is so marked in some cases that an actual stream of sweat is set up. The fact is of importance with refereuce to the question of the sudorific axillary secretion that is considered to depend upon electrical excitation of the rhachidian and costal regions. The author has not succeeded in obtaining, by the same means, the secretion of sweat in the axilla, if care was taken to avoid exposure of a considerable area of the skin. This supersecretion, after the author, goes to show also that the reflex vaso-constricting influence of cold is not so general as is supposed.

2. Epileptic patients have been observed to be enabled to avert an epileptic fit by swallowing quickly a glass of cold water just at the beginning of this premonitory obnubilation; this means proved to be fruitless when it was too near the period of loss of consciousness. The following observed phenomena are given as an explanation to account for the above effect: By means of Bloch's sphygmometer the patient's arterial pressure during the normal state has been ascertained to be from 800 to 850 grammes; after the sudden ingestion of twenty-four centilitres of ice-water, the arterial pressure amounted to from 1,050 to 1,200 grammes. Within a period of from five to six minutes after the ingestion of the liquid the pressure returned to the normal standard. The augmented arterial pressure has been observed to be less in case the same quantity of cold water is ingested in divided doses.

The augmentation of the surface blood-pressure is explained by the constricting action of the cold on the abdominal vessels. The occurrence of syncope and other accidents under the influence of ingested cold is presumed to depend upon a possible reflex constriction of the encephalic vessels.

Assuming that the increased blood-pressure constitutes one of the physiological conditions of an epileptic discharge, it is questioned if the artificial induction of high blood-pressure, as is the case in ingesting cold, does not act by substitution, causing at the same time a partial spasm capable of interfering in due time with the epileptic discharge.

By subjecting one hand to a temperature higher than the surrounding, and so determining in that hand a greater amount of blood, M. Féré has been successful in realizing the counter-proof of the fact that, in general, psychomotor excitations, or depressions, are characterized respectively by an augmentation or diminution of the energy of voluntary movements, and shortening or lengthening of the period of reaction.

On the Retrograde Circulation in the Venous Blood-Current.—M. J. Thomayer (*ibid.*) alludes to the fact that auscultation over markedly dilated varicose veius of the lower limbs at the time when the patient is straining, as during cough or other exertion leading to contraction of the abdominal wall, gives frequently a murmur identical to the *bruit de diable* of anæmic patients. Touching the dilated vessel gently with the finger, the *bruit de diable* is felt to be induced by a jerk of blood propagating in the vein from the center to the periphery, at the moment that the patient coughs or exerts contraction of the abdominal muscle. In cases of general dilatation of the saphenous vein, narrowing of the same by gently compressing it gives the same murmur below the point of compression.

M. Thomayer sees as cause for the murmur the retrograde blood-curreut occasioned by the intrathoracic or intra-abdominal pressure. He thinks that in the normal blood-vessels the same phenomenon takes place under the influence of the same agents; this retrograde circulation must take place, it is supposed, if not in general, at least in the veins of the lower limbs at the level of the first venous valves. Basing his idea on the existence of the current under pathological conditions, in varicose veins, the author is inclined to accept it as a possible normal physiological phenomenon, though it can not be obtained as such, for the reason of its propagation being interfered with by the venous valves; he supposes that physiologically it exists at least in the vena cava inferior, and in other veins deprived of valves. He points out that the interest that this fact offers is that it explains the origin of the retrograde metastasis described by von Recklinghausen, and also disturbances of circulatiou occurring in diseases accompauied by cough and tenesmus; it finally shows that the *bruit de diable* in anæmia depends upon the venous walls (dilatation?) rather than upon the pathological condition of the blood.

On Exploration of the Movements of the Tongue.—By modifying M. Bloch's apparatus, M. Ch. Féré (*id.*, No. 15, 1889) has constructed a glosso-dynamometer that enables him to study the resistance to pressure of the tongue in its five principal directions. He thinks this contrivance will prove of good service in the study of neuropathic disturbances of the tongue.

The description of the mode of application of the instrument is given, and it is stated that under normal conditions the resistance to pressure from above downward, or the energy of the movement of elevation of the tip of the tongue, varies from 700 to 850 grammes; that of lowering, from 600 to 800 grammes; the resistance to lateral pressure is from 600 to 850 grammes; and, finally, protruding the tongue resists a pressure of from 700 to 900 grammes.

These measurements are well utilized in unilateral disturbances of the tongue. The author opposes the generally admitted belief that disturbances of articulated speech can exist without at the same time alteration of the movements of the tongue; for, he states, the cerebral organs of sensibility or movements are the seat of reflex phenomena, and descending degeneration is possible in cases of lesions in Broca's region, as well as in cases of lesions of the motor regions. Direct explorations show the coincidence of disturbance of lingual movements with that of articulated speech. The statement is confirmed by the following facts:

1. In two aphasic patients with slight hemiplegia there was no apparent alteration of mobility of the tongue, and examination revealed decreased resistance to pressure that amounted to from 250 to 300 grammes on the right side; the movements of elevation, depression, and protrusion were from 100 to 200 grammes less than the uormal.

2. In three hysterical patients that had been aphasic by suggestion

the diminution of resistance to pressure from right to left amounted to from 200 to 300 grammes.

3. In several epileptic patients with speech disturbances subsequent to an attack, the resistance to pressure was diminished to various degrees in all directions. On an average it is 200 grammes below that obtained in the same individual about two or three hours after the attack.

4. A general paralytic patient with marked disturbance of speech gives almost negative resistance in all directions, though he performs conscious efforts and makes free movements of the tongue in every direction.

5. A congenital deaf and dumb subject presented diminution of resistance in all directions amounting to from 280 to 300 grammes.

The author further says that M. Charcot's statement of the existence of unilateral glosso-labial spasm on the side opposite to the paralyzed half of the body in hysterical patients, and M. Bressaud, M. Marie, and M. Bélin's confirmation of the frequency of the occurrence of this symptom, must be accepted with reserve, for, in eight hysterical patients affected to some extent with hemimyasthenia of the limbs, he found decreased resistance of the tongue to pressure on the side correspondiug to the paralyzed half of the body. In three cases with marked myasthenia the lingual resistance on the side corresponding to the affected side of the body was almost absent, whereas on the opposite side it amounted to from 650 to 700 grammes.

On two of those patients that presented right anæsthesia and amyasthenia the author observed that, under the influence of suggested aphasia, the lingual resistance on the same side was still further reduced, while the increase on the left side was 50 in one and 100 grammes in the other patient.

Similar facts are stated to be of frequent occurrence in hysterical patients and in those subject to suggested paralysis.

On Lavation of the Blood in Infectious Diseases.—MM. A. Dastre and P. Love (*id.*, No. 14, 1889) related in the *Arch. de phys.*, 1888, their studies on intravenous injections of water, in which it was demonstrated that, by observing certain precautions, a considerable quantity of water can be introduced into the circulatory apparatus without causing any accidents to the animal. The injected liquid passes from the blood into the tissues, returns back into the blood, and the excess of water is finally rejected by the kidneys.

It was shown also that the rejected excess of water did not contain any essential elements to nutrition, but indifferent ingredients and urea particularly was swept away by the process of lavation.

On the strength of this, the authors expected that, in case of blood infection, lavation of the blood would lead to artificially increased elimination of harmful substances introduced into the system either directly or by intoxication. In all cases of experimental intoxication where the method of lavation was used, though the quantity of secreted urine was increased, the animals succumbed always an hour before those in which the disease was left to its natural course.

The authors suggest two points in explanation of the acceleration of the course of infection: First, under the influence of the operation of lavation the vital resistance is considerably diminished; this diminution is of little consequence in the normal organism, but under pathological conditions serves to aggravate symptoms. Secondly, by lavation infectious matter is diffused and distributed in all parts of the body, and this hastens to lessen the vital resistance of the tissues.

The presumption that the increased elimination of urine would interfere with or compensate for the artificial supply of poison in the experiments not having been realized, the authors suppose that either the toxic matter generated by the microbes is not at all filtered by the kidneys, or else this is done in a deficient measure. Upon this subject they expect to dwell in future.

The Passage of Oxyhæmoglobin into the Gall-bladder after Death.—MM. E. Wertheimer and E. Meyer (*id.*, No. 26, 1889) relate that the gall-bladder taken from an animal that was killed two or three hours previously contains almost always oxyhæmoglobin. Experiments contradict the hypothesis that this is due to post-mortem secretion that is furnished by the dead hepatic cells, whose diminished activity leads to incomplete elaboration of the coloring matter of the blood.

The experiments consist in ligating the cystic duct immediately after the death of the animal; the oxyhæmoglobin occurs as before; the same takes place on extirpating the gall-bladder and exposing it to the air for several hours.

The explanation given is that it depends upon a cadaveric phenomenon the mechanism of which is probably the following: The vesicular epithelial lining losing its vitality, allows transudation of the bile through it and its blood-vessels; the red blood cells are dissolved by the action of the bile, the oxyhæmoglobin is discharged, and then diffuses toward the cavity of the gall-bladder, mixiug at the same time with the bile contained therein.

The same observations have been made on different animals, dogs, rabbits, guinea-pigs, and on some specimens of bile taken from cadavers.

The authors had announced as a peculiarity the fact of the almost constant presence of oxyhæmoglobin in the bile of animals with an artificially reduced temperature. At present they are enabled to interpret the fact, and do not admit now the peculiarity to depend upon the artificially reduced temperature. The more constant presence of oxyhæmoglobin in the bile of animals that died a normal death than in that of animals killed by means of freezing is ascribed to the reduced vitality of the hepatic cells in the latter.

It is suggested that it might prove of service in legal medicine to determine the exact moment of the occurrence of the cadaveric alteration, having as a guide the occurrence of oxyhæmoglobin in the bile.

On Nutrition in Hysteria.—The literature on the subject shows that all authors agree with M. Empereur, who, in his essay on the nutrition in hysteria (1876), concluded that the assimilation in hysterical subjects was absent, because disassimilation did not take place. He formulated the same by saying: "Elles ne maigrissent pas parce qu'elles ne déperdent rien, et, ne déperdant rien, il leur est inutile, sinon nuisible, de manger." M. Gilles de la Tourette (*id.*, No. 30, 1889), with his interne in pharmacy, M. H. Cathelineau, undertook to contribute to the same question on the ground of the urinary excreta in hysterical patients of both sexes. They divide the patients into two groups: 1, normal, and 2, pathological hysterical patients, the first being those that possess permanent physical stigmata establishing the diagnosis of the neurosis, and the second those presenting, in addition, the series of the various accidents characterizing a full hysterical fit.

I. Ten hysterical persons of the first group, including seven women and three men. were examined, and it was found that, though it was true that they did not accept, as a rule, the ordinary food, yet in the particular food that they often had a desire for exclusively they found enough of nourishing material sufficient to keep even a normal person in a good condition of health. From seventy-nine analyses of specimens of urine voided in the twenty-four hours, the examination having reference to the volume, solids, urea, and phosphoric acid, the authors conclude that in what they called normal hysterical patients the nutrition differs in no respect from that in normal persons.

II. In the patients of the second group the pathological phenomena regarding the attack were studied specially with regard to: 1, the convulsive attack in four periods; 2, the attack limited to one of these periods, or having in this period a predominating epileptoid, lethargic form, etc.; 3, the attack of the type of partial epilepsy; 4, the attack of rhythmic chorea, cough, yawning, etc.

The urinary analyses for the twenty-four hours, comprising the time from the beginning to the end of the attack, enable the authors to state that in a convulsive and the various other hysterical attacks there is—1, decrease of the urinary solids, of the urea and phosphates; 2, the ratio of the earthy to the alkaline phosphates being normally as 1 to 3, becomes during an attack as 1 to 2, and often as 1 to 1. This the authors called inversion of the formula of phosphates.

The volume of the urine for the twenty-four hours is more frequently diminished, though the first micturition following the attack is generally greater than an ordinary one, and this leads to the polyuria, when the latter exists.

The authors think that chemically the various grave forms of hysteria—epileptoid, cataleptic, delirious, lethargic, etc.—are to be considered simply as prolonged hysterical attacks with accentuation of all phenomena that are observed in a simple attack.

From the study of the curve of urinary excreta during the period of an attack it is concluded that there is a decrease in the urinary elements in the beginning of the attack, then a return to the normal, and finally an increase before the discharge of the attack. This increase, it is said, before and during the day of the attack does not depend upon the alimentation; the latter has been negative in most of the patients that were under observation during the attacks. It is inferred from the fact that the phenomena are dependent upon the hysterical attack itself, and not upon inanition.

Clinically the importance attached to the fluctuation of the curve of the urinary excretions is that it enables to foresee the extent of the duration of the coming attack, and to predict the return to the normal condition.

Regardless of the variety of the attack, the body is said to lose in weight during this period, and, according to its duration, from 200 to 300 grammes per day, and to return rapidly to the normal after the attack.

The statements are illustrated by the following tables of urinary analyses:

Comparison between Partial Symptomatic and Partial Hysterical Epilepsy.

NAME.		Volume of urine.	Solids.	Urea.	PHOSPHORIC ACID.			Relation between the phosphoric acids.	Observations.
					Earthy.	Alkaline.	Total.		
		C.C.	Grm.	Grm.	Grm.	Grm.	Grm.

Coexistence and Differentiation of an Hysterical Attack and an Epileptic Access in the same Person.

Patient, age 21; weight, 72 kilos.	Normal state.	1,150	44·40	22·00	0·70	1·72	2·42	40 to 100	Normal state.
	Attack.	1,350	33·00	14·00	0·56	0·92	1·48	63 to 100	Hysteria.
	Access.	1,320	48·00	27·00	0·87	2·05	2·92	42 to 100	Epilepsy.
Patient, age 28; weight, 61 kilos.	Normal state.	1,200	52·15	24·00	0·57	1·73	2·30	32 to 100	Normal state.
	Attack.	1,190	41·00	18·00	0·76	1·20	1·96	63 to 100	Hysteria.
	Access.	1,150	56·20	31·05	0·69	1·88	2·57	36 to 100	Epilepsy.

On the strength of the urinary analysis, M. Empereur's conclusions are pronounced erroneous.

It is shown in the table that chemically a hysterical constitutes the reverse of an epileptic attack. An attack of true or partial symptomatic epilepsy is to be recognized by the considerable elevation of the urinary constituents, whereas a hysterical attack in shape of any of its various forms is to be recognized by a considerable diminution of the same. In two cases of hysteria with stigmata without attacks the authors recognized the coexistence of true epileptic accesses. In conclusion, it is said that this work is the first that positively establishes the diagnosis in doubtful cases.

Anæsthesia in Frogs by Deficiency of Oxygen (Presented by M. Morat).—M. Reboul (*id.*, No. 22, 1889) produces asphyxia in the frog either by exclusion of air or keeping it in a vessel with inert gas; after a certain time the frog becomes immobilized and insensible. With preservation of the circulatory movements the frog gives all symptoms observed in ordinary anæsthesia. Exposing it to the air, it gradually returns to the normal.

The author suggests the use of this method of anæsthetization for delicate experimental work on cold-blooded animals. Physiologically, the fact is mentioned to be of interest from the view that, under the influence of asphyxia by privation of oxygen, the properties of the nervous system disappear gradually in the order observed under the action of the ordinary anæsthetics.

On the Lowering of the Body Temperature in Men after suggested Loss of Sensibility to Heat and Cold.—M. M.-J. Marés (*id.*, No. 24, 1889) had stated that in mammalia the hibernal sleep was a hypnotic phenomenon in which the animal lost the sensibility of cold, which is the principal regulator of temperature in hæmothermic animals; that by artificially reducing the body temperature a warm-blooded animal was converted into a cold-blooded one, and fell into hibernal sleep. With the return of the sensibility to cold there is an increase in the production of heat by reflex way; the animal resumes the physiological temperature and is free from hibernal sleep. On the strength of this theoretical consideration, M. J. Marés undertook a series of hypnotic experiments which proved fruitless on animals but successful on men. The results are elaborately represented in figures that show the decided influence of suggested loss of sensibility to cold and heat on the physiological temperature.

In one case the sublingual temperature is recorded to have been 37·1° C. at 8.30 A. M., and 34·5° C., after the suggestion, at 8.30 P. M. In another the figures were, respectively, 37° C. at 8.30 A. M., and 35·5° C. at 8.30 P. M., after suggestion.

In both cases, after restitution of the sensibility to cold, all unpleasant symptoms subsided, and the temperature returned to the normal.

The phenomenon is supposed to be due to disturbance in the regulation of the temperature caused by the hypnotic suggestion of loss of sensibility to cold, by virtue of which the external loss of body heat surpasses the proportionate internal supply, until finally the thermic source is exhausted and there is actual interference with the normal equilibrium between the loss and repair of heat production.

MM. Marés and Hellich think for this reason that the influence of suggestion is not limited to the functions of volition and consciousness; they do not accept Bernheim's statement of the suggestive influence being purely psychical.

It is further said that the lowering of the body temperature subsequent to suggested loss of sensibility to cold and heat is a physiological experiment indicating the causal connection between the sensibility to cold and the production of heat, and that this sustains the doctrine deduced from experiments by physico-chemical methods that the sensibility of the nervous system to heat and cold is the main regulator of the constancy of temperatue in warm-blooded animals.

It is put forward as a proved fact that hibernal sleep is a hypnotic phenomenon in which the animal loses sensibility of cold, and that men too, by losing sensibility to temperature, fall into hibernal sleep or apparent death. The surprising tales about the Indian fakirs seem to the authors to depend upon auto-hypnosis leading to loss of sensibility, which is followed by complete inertia of the nervous system suspending all vital functions.

On the Influence of Oxygen Inhalations on the Variation of the Respiratory Rhythm in Diphtheritic Patients.—In the Children's Hospital M. P. Langlois (*id.*, No. 13, 1889) has experimented on children with infectious diphtheritic angina without the existence of a false membrane in either the larynx or the trachea, and on those that presented all the symptoms of croup before and after tracheotomy. About thirty litres of oxygen were used for each case within from twenty to twenty-five minutes. The respiratory tracings were taken by means of Marey's double cardiograph.

The modifications of the form of the respiratory movements under similar circumstances had been studied already by Ledoux-Levard (*Recherches sur la respiration dans le croup*, Thèse, 1881), and the author paid special attention to the variation in the frequency of the same movements.

Acceleration of the respiratory rhythm during the oxygen inhalations was observed as a constant result. It begins with the inhalation and lasts as long as this is maintained.

Though the frequency of the respiration is increased, it is of a less dyspnœic character. Both inspiration and expiration are more brisk and energetic, and performed with less difficulty. The child is more in a condition of polypnœa than of dyspnœa.

The acceleration of the respiratory rhythm caused by oxygen inhalations seeming to be in contradiction with Rosenthal's statement of the rôle of anoxæmia as an exciting agent of the respiratory center, M. Langlois explains as follows: Under the influence of prolonged subasphyxia depending upon laryngeal stenosis, and perhaps upon the

specific action of the secreted septic product of the diphtheritic micro-organisms, the entire organism, and the bulbar centers particularly, are oppressed, which causes diminution in the respiratory incitations. But under the influence of the inhaled oxygen the superoxidation of the blood diminishes the vital depression, and the child reacts quickly in resuming sufficient pulmonary ventilation.

Hæmatospectroscopic Notes on Hysterical and Epileptic Subjects.—M. Ch. Féré (*id.*, No. 7, 1889) has reported the comparative examinations of hysterical and epileptic subjects, and has found the duration of reduction to be longer on the anæsthetic side in hysterical persous. The duration of the disappearance of the principal hæmoglobin band in the same varies greatly, and the conditions of such variations can often be determined. Thus, in induced sleep it is augmented; there is decided augmentation especially in lethargia; in one such case the duration amounted to 88″, instead of 72″, and in another to 82″. instead of 63″. In somnambulistic subjects the duration of reduction can be varied either by inducing different emotional conditions or simply by exciting the organs of special senses. M. Hénocque had already mentioned that in normal subjects muscular exercise and massage lead to augmentation of the activity of reduction; the momentary effect of muscular exercise, massage, hydrotherapy, and static electricity is to increase decidedly the activity of reduction in hysterical persons. The influence of cutaneous excitations, or of excitations of the special senses, is manifested with the same intensity. Suggested emotions in somnambulism, persisting during the period of consciousness, give analogous variations; sthenic emotions are accompanied by a diminution, and asthenic by an augmentation of the duration of reduction.

With reference to the phenomena of nutrition in relation to the normal psychical conditions, Apjohn (*Dublin Hosp. Rep.*, 1830, v, p. 532) had contributed an observation on his own person, stating that there was considerable diminution of the exposed carbon dioxide under the influence of temporary mental depression.

M. Féré has been enabled to observe in hysterical persons, in whom the activity of reduction is already decreased, a still further augmentation of the duration of reduction under the influence of suggested depressive emotions.

The lowering of the nutritive process is in relation not only with depressive emotions, but, too, according to M. Hénocque, with the mental or physical fatigue, and subsequently with exaggerated activity following marked peripheral or mental excitations. In case the duration of reduction, under these conditions, is not increased, it is to be ascribed to the fact that excessive nervous discharges are apt to be followed by a diminution of the quantity of oxyhæmoglobin.

Accidental lowering of nutrition, occurring in the course of mental depression and subsequent to marked excitations, can serve as a basis of explanation of the fact that any nervous discharges—such as psychical or mental fatigue, traumatic or moral shock—are apt to contribute to the diminution of the feeble nutritive activity of certain subjects, and induce what M. Bouchard called "maladies par ralentissement de la nutrition," this affection being more apt to manifest itself on the side of the body previously predisposed by other disturbances. The diminished resistance to intoxication and infectious diseases under the influence of depressing conditions is to be explained by the existing diminished nutritive processes. The knowledge of the modifications of the activity of exchanges, under the influence of peripheric excitations, that might be manifested as either mental or moral emotions, contributes to the admission of the intimate correlation between the psychical and moral conditions. Comparing the variation of the duration of the oxyhæmoglobin reduction with that of the time of reaction in hysterical persons, M. Féré says (*id.*, 1889, p. 671, Note sur le temps de réaction chez les hystériques et les épileptiques) it is evident that both phenomena undergo parallel variations under the same influences. Though it is impossible to establish definite proportions, it is permissible to state that the duration of the time of reaction varies as the duration of the oxyhæmoglobin reduction, or, as the author states, in other words, the time of intellectual activity is in relation with the activity of nutrition. Mental pathology can furnish, it is said, other illustrations demonstrating that intelligence is a function of the nutrition. With M. Hénocque, the author refers to the diminution of the activity of the oxyhæmoglobin reduction in epileptics, adding that this accident coincides with the existence of a reduced quantity of oxyhæmoglobin in the blood, as he found it in his observations on epileptic patients to be nine per cent., whereas, according to M. Hénocque, general patients of the hospital present thirteen per cent. of oxyhæmoglobin. Among the different causes that could account for the decidedly reduced percentage of oxyhæmoglobin in epileptics the author is convinced that an attack is the main factor, for always after the attack he found the relative reduction to amount to from one to two per cent., this disappearing within the few days following the attack.

The reduction manifests itself not immediately following the attack, but some time after, which has not been determined as yet; it amounts to over three per cent., regardless even of the forced alimentation that may be administered to the patient. This fact, it is said, corresponds with the statement of the decreased quantity of oxyhæmoglobin subsequent to intense uervous discbarges; it serves also to explain the occurrence of acute anæmia consequent on violent emotions (D. Duckworth, On Acute Anæmia due to Fright, *Brit. Med. Jour.*, 1873, ii, p. 226).

The author thinks it possible that the blood alteration is an important factor in the cause of death during the stage of an epileptic attack.

All this goes to show the relation and coincidence of mental troubles with defective nutrition. The deductions from that knowledge and the practical indication based on the same, M. Féré states, have already been dwelt upon by Weir Mitchell.

On Auto-intoxication of Renal Origin, with Elevation of Temperature and Dyspnœa.—M. R. Lépine (*Abeille méd.*, No. 27, 1889). The contrast is drawn between the effect of ligating the ureters and the introduction of a cannula into the same, the cannula communicating with a reservoir that contains water, to which some sodium chloride is added in the proportion of 0·7 per cent.; the pressure of the water is made sufficient to interfere with the outflow of urine, and to somewhat fill the kidney with this solution. In case the ureters are ligated the animal succumbs within about three days; with the gastro-intestinal irritation there is lowering of the central temperature. In the second case the symptoms of vomiting and diarrhœa are absent, but foaming at the mouth is present; both the central aud peripheral temperature rise progressively, and almost at the same time the respiration assumes a special expiratory type—is lowered at first, then much accelerated and becomes noisy; sometimes there is some subsultus of the limbs; the central temperature continues to rise, and within a few hours the animal succumbs with a temperature varying from 40° to 42° C. As soon as this temperature is reached nothing can prevent the fatal issue, even if the urine is allowed hastily to flow as usual. It is not admitted that the accident is due to the entrance of water into the renal system, since intravenously a considerably larger quantity of saline water can be infused without provoking any fever or other disturbances; but the water passing through the renal system is charged with renal interstitial juice, acquires a thermogenic and dyspnœic action. The noxious effect of this interstitial juice of the kidneys is confirmed by the following experiment: The kidneys of a dog killed by acute hæmorrhage are crushed in sterilized water, and after filtration an intravenous injection of the liquid is made in a smaller dog. At the lapse of four hours the central temperature rises to 40·1 C., the animal is oppressed, there are agitation and foaming from the mouth, the symptoms being the same as those obtained from au animal subject to urinary counter-pressure.

The conclusion is that the healthy kidney contains thermogenic, dyspnœic, and other principles. This the author admits optionally, for in his experiments either one or the other poison predominated, as could be judged from the symptoms.

A Case of Association of Cardiac Inhibition with each Inspiratory Effort.—M. L. Capitan (*Arch. de phys. norm. et pathol.*, No. 3, 1889) quotes Brown-Séquard's recent experiments, demonstrating that pronounced respiratory movements—such as are observed in dogs that are made to breathe in an atmosphere mixed with carbon dioxide—are apt to completely inhibit the heart during either the inspiratory or expiratory act.

The author had an opportunity of observing carefully the occurrence of similar phenomena in a human subject.

The patient poisoned with morphine remained in complete coma during twenty-four hours; no therapeutic agent could arouse him. The

respiration was exceedingly rapid, deep, regular—from 32 to 36 per minute. The pulse was very rapid, quick, tolerably strong and regular—from 160 to 180 per minute. Toward the twenty-sixth hour, the respiratiou maintaining its previous type, the pulse presented a rhythmical irregularity with distinct periods of suspension, and within the four succeeding hours was characterized by the following peculiarities: The expiration lasted from one to one second and a fraction; during this period five pulsations could clearly be counted. At the moment of the beginning of inspiration the pulse was suspended, and no pulsation could be felt during the entire period of inspiration, which lasted for about half a minute. With the commencement of expiration the pulse reappeared, beating again five times during this period. The cardiac beats could not be obtained distinctly for the reason of the presence of numerous râles in the chest. This cardiac inhibition during inspiration lasted in a very regular manner until the thirty-sixth hour. Both respiration and pulse diminished in amplitude and intensity respectively, the former having ceased progressively, then the pulse, which presented the same peculiarity to the last during one of the acts of respiration.

The author thinks that the fact confirms distinctly Brown-Séquard's statement.

Appearance of Red Marrow in a Case of Acute Anæmia.—M. Lépine (*Lyon médical*, No. 22, 1889) presented to the Société des sciences médicales a transverse section of the superior portion of the femur, taken from a woman seventy years of age, who had died of acute hæmorrhage. The bone marrow was colored red, as in infants, instead of being adipose.

M. Augagneur questions whether the profound anæmia in tertiary syphilis has not its origiu in the bone lesions, taking into consideration the persistence of interference with hæmatosis aud its being accompanied with the train of symptoms of osteocopic pains and gummatous infiltration of the bones.

M. Lépine states that in similar syphilitic cases he has found in the red marrow large cells holding in their interior blood cells. The former are supposed to absorb the latter, and then destroy them.

In this connection Cohnheim is quoted, in his description of red marrow containing cells of a transitory type between marrow and blood cells.

M. Lépine thinks, without giving actual demonstration, that this special coloration of the marrow is met with in the bones of the entire skeleton; he has found this in the stermun, humerus, and femur. M. Augagneur thinks the characteristic of the marrow is the presence of what are called myeloplaxes containing red cells, which are considered by some authors as the result of inflammation.

New Inventions, etc.

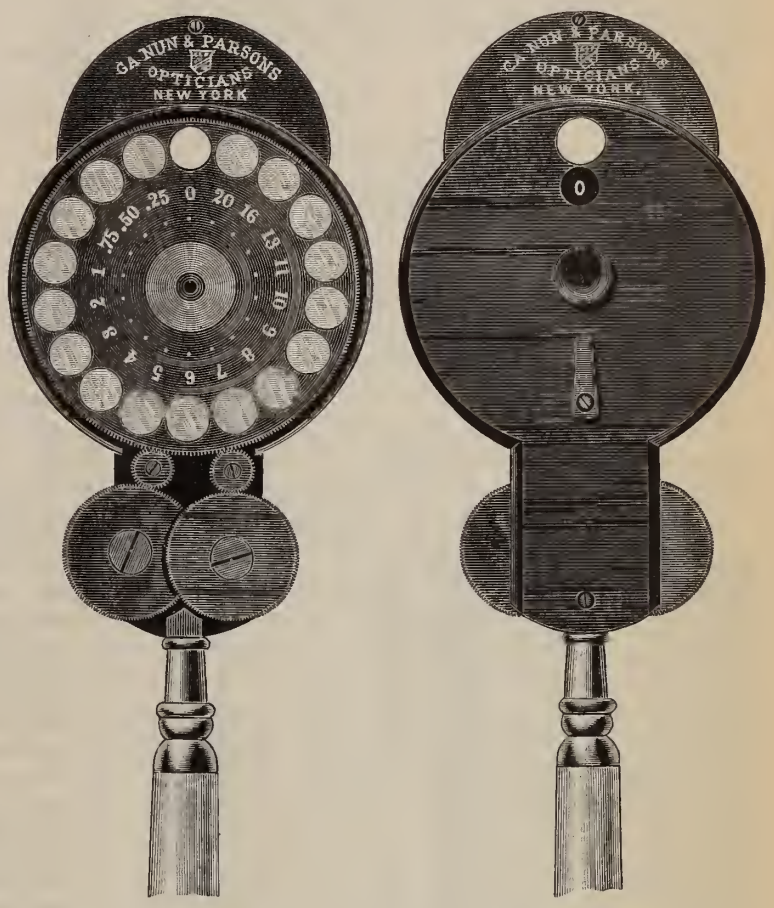
A NEW OPHTHALMOSCOPE.

By S. M. Payne, M. D.,

LECTURER ON OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC; ASSISTANT SURGEON, MANHATTAN EYE AND EAR HOSPITAL.

Having had considerable experience with various ophthalmoscopes handed to me by beginners in ophthalmoscopy, to explain their manner of working, and also the experience of making examination of eyes with them, I found none of them that exactly filled the requirements in all cases. In some of the single disc ophthalmoscopes there is too great a difference in the strength of the lenses to make a minute examination of the fundus, correspouding to the examination made with the test lenses. In other single disc ophthalmoscopes the strongest lens is not sufficiently strong to make a minute examination of the cornea and lens.

The improved Loring, which is now more in use than any other, has some objections. Experience has proved to me and others that one can not see as distinctly through two strong lenses as through a single lens of the same strength as the two combined. Another objection is that it has to be removed from the eye every time a change is required, which is not a very small matter if one is pressed for time. Some other ophthalmoscopes are too mechanical, without sufficient combinations of the weaker lenses, and sufficient in the stronger lenses only by a combination of two.



The ophthalmoscope I have devised has two discs—one with convex and the other with concave lenses of seventeen each, the numbers of which are the same in both discs, running, as you will see in the cut, as follows: 0·25 D., 0·50 D., 0·75 D., 1 D., 2 D., 3 D., 4 D., 5 D., 6 D., 7 D., 8 D., 9 D., 10 D., 11 D., 13 D., 16 D., and 20 D. The last eight have focal distances in inches—5½″, 5″, 4½″, 4″, 3½″, 3″, 2½″, and 2″—which are sufficient without interposing another lens. Each disc is supplied with a revolving wheel immediately below and just above the handle. Moving down the wheel on the right side increases the strength of the convex lenses to the right, aud moving down the wheel on the left side increases the strength of the concave lenses to the left. The wheels are very easily manipulated with the thumb for one and the index finger for the other. In measuring an eye to correspond with the result obtained by the test lenses, every 0·25 D. can be obtained, on either disc, up to 11 D., by placing 0·75 D., 0·50 D., 0·25 D. of the opposing disc over each successive lens, after the first four lenses, which differ by 0·25 D., without combination; and every 1 D. from 11 D. to 20 D. can be obtained by placing of the opposing disc 1 D. over 13 D., 2 D. and 1 D. over 16 D., and 3 D., 2 D., and 1 D. over 20 D. You will notice that the strongest lens used iu combination with a strong lens is 3 D., which is used only to make one combinatiou, 2 D. only two, and 1 D. only three combinations. The combinations of the opposing 1 D., 2 D., and 3 D. are only necessary in the refraction of a high degree of myopia, as the refraction of hypermetropic eyes does not run higher than 11 D., including aphakia. Another good feature of its

working is that, while looking at the front of an eye with the + 20 D., one downward move of the right wheel brings the fundus into view; by looking only through the aperture, if very indistinct, one upward move of the left wheel will bring — 20 D. over the aperture, two moves — 16 D., and so on, quickly finding if myopia exist, and the amount. Every turn of one or both discs will give any combination found in the most complete test case without taking the ophthalmoscope from the eye. The mechanical construction of the instrument has been very perfectly carried out by Messrs. GaNun & Parsons, opticians, of 5 West Forty-second Street.

266 Madison Avenue.

Miscellany.

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for July 25th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—									
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.
New York, N. Y.	July 19.	1,633,748	941	..	..	..	..	..	..	5	7	13	11	15

Poisoning by Antifebrine.—"Dr. J. Vierhuff, of Subbath, in Courland, communicates to the *St. Petersburger medicinische Wochenschrift* the notes of a case of antifebrine poisoning, which show what dangers people run who dose themselves with drugs of this class. A healthy young married woman, who had been in the habit of taking antifebrine for headache, feeling the pain come on early one morning last summer, took, fasting, about a teaspoonful of the drug in some water. In about ten minutes, the headache not being relieved, she repeated the dose, which her husband remarked might prove dangerous. She consequently took a glass of milk and some alum water in order to produce vomiting, which she succeeded in doing, but immediately afterward giddiness, singing in the ears, throbbing in the temples, and a dull pain in the head, together with a feeling of weakness, came on, and the face assumed a livid hue. When seen four hours after the drug had been taken the face was a livid color, the lips blue, the pupils contracted, but the heart, temperature, and mental condition were normal. An aperient and a stimulant were ordered. Shortly afterward the patient became suddenly collapsed, the pulse could not be counted, and the breathing was very shallow; in fact, the woman appeared to be dying. The soles of the feet were brushed, vinegar was rubbed on the face, and cold water sprinkled over the face and chest; also a mixture of camphorated oil and ether was ordered for injecting subcutaneously. While this was being procured several syringefuls of dilute spirit, which was all that could be obtained, were injected and the patient was brought round, though for three hours and a half her condition appeared hopeless. Then, after recovering somewhat, collapse again came on, and recourse was had to an intravenous injection of a solution of common salt, which appeared to act most beneficially. In about fourteen hours after the drug had been taken the patient was out of danger. After that she continued to improve, though she complained of debility and pain in the limbs for a week. Dr. Vierhuff remarks that the serious symptoms were probably due largely to the patient's taking the antifebrine on an empty stomach."—*Lancet.*

ANSWERS TO CORRESPONDENTS.

No. 327.—The new law has not gone into effect. If you have a New York State diploma, you have only to register at the County Clerk's office. If your diploma was not issued by a New York State college, you should have it certified to by Dr. Austin Flint, and then register at the County Clerk's office.

No. 328.—In Buffalo.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Original Communications.

THE PRESCRIPTION OF EXERCISE.*

BY THOMAS M. BULL, M. D.

IT is the object of this paper not so much to lay down certain rules in regard to the best method of developing the body by exercise, and to bring forward facts, figures, and specimens to prove these statements, as to lay before your minds a few ideas of what may be gained by exercise, and to give a brief description of some general principles touching their application.

I do not intend to advance anything new or startling, but merely to present a few ideas, partly the result of practical experience and partly theoretical, which may help somewhat when next you wish to prescribe exercise.

It is a well-known fact that eminent physicians of the same school even, and sometimes the attendants at the same hospital, treat the same diseases in very different, often in diametrically opposite, ways. Frequently a well-known practitioner comes forward with a series of cases of some severe malady treated with colored water, from which the results were as good or even better than from the employment of regular methods. The irregulars of every school, from those who use sugar pellets to those who use only faith and prayer, are very fond of exhibiting their cures and challenging comparison with the regular practitioners. The idea of giving specific drugs for certain diseases is pretty well abandoned with the exception of a very few; and even the famous elixir of life, which a few short months ago promised so much, has been dropped into oblivion.

It is owing to this general chaotic condition of medicinal therapeutics that in the last few years the attention of physicians has been much more generally given to methods of cure and prevention which did not involve the giving of drugs. As a consequence, the science of hygiene has been more thoroughly investigated lately, and the therapeutic uses of such measures as external applications, electricity, cold and heat, diet, climate, baths, massage, and exercise are more often employed now than ever before.

It is only with the consideration of the last of these measures that this paper is concerned, since it has seemed to me that not enough prominence has been given by physicians to the beneficial effects which come from muscular exercise properly taken. One reason why physicians have not prescribed exercise more is probably because they have not had the time to look into the subject thoroughly and see what may be accomplished by it. Another is from the difficulty in getting busy people to carry out these prescriptions, and still a third is because physicians, not having a right idea of how certain ends were to be accomplished, had recommended exercises which, although faithfully carried out, would not achieve what was wanted.

For a doctor to tell a patient to "take exercise" is about equivalent to saying "take medicine," and is likely to be followed by about the same results. A patient may injure himself by taking exercise of the wrong kind, quantity, or intensity, the same as by taking a wrong drug or dose. The sooner doctors realize that they must be more specific and careful in prescriptions of this character the better. It is also as important to make the exercise pleasant as it is to make medicines palatable; otherwise it will not be taken regularly or with any relish. In order to prescribe exercise with benefit it is necessary to have clearly before our minds what may be accomplished by it. The following seem to be the most common indications for its prescription:

1. To preserve the health of sedentary people.
2. To reduce deformities.
3. To alter weight.
4. To overcome a tendency to hereditary and organic disease.

I. Every physician is familiar with the long list of ills which are certain, sooner or later, to fasten on those who lead strictly sedentary lives—headache, nervousness, sleeplessness, neuralgias, disorders of the stomach and liver, constipation, hæmorrhoids, and the thousand and one indefinite ailments which render life miserable both to the patient and physician. All of these can to a large extent be prevented, and most of them benefited and cured, by exercise properly regulated as to time, amount, and accompaniments. Exercise acts here as the great balance-wheel to keep up constant motion in all parts. It will enable the sedentary man to eat and digest more, to sleep better, and to go at his work with a greater vim than any other thing. What the special indications are for each one of these disorders it would probably be useless to try to discover or carry out. But the general rules in prescribing for sedentary men are as follows:

1. Consider the man and prescribe something which can be carried out. Don't tell a clerk on eight dollars a week to go horseback-riding at two dollars an hour, or try to have a two-hundred-and-fifty-pound man ride a bicycle, because these means are those you enjoy. Don't try to force the inland resident to row, or the one who dwells at the seaside to climb mountains. All are good enough in their places and in proper cases, but as a prescription they are not so likely to be carried out as something more suitable.

2. Whatever you prescribe to patients, have them begin gradually. The novelty of a thing will be apt to make a man overwork at first, in which case he is sure to be disgusted the next day and not likely to try it again if he thinks he will have the same experience. I have known a piano player so used up by his first few minutes with a pair of Indian clubs that he never touched them again. So always give the caution and tell them that if soreness or stiffness follows, it will quickly wear away, and soon no amount of exertion will make them sore.

3. Whenever you prescribe exercise of any kind, be sure you are acquainted with the state of the heart, lungs, and arteries of the patient. Also see if he is ruptured or liable to be. It will certainly increase his respect for you and

* Read before the New York County Medical Association, June 16, 1890.

make him more apt to follow out your prescription if you insist on inquiring into these matters before prescribing. A man liable to apoplexy on excitement or afflicted with a double aortic murmur certainly ought not be in a foot-ball rush line, or one with a commencing inguinal hernia in a tug-of-war, and a great deal of the odium which, in the minds of many, rests on athletics, might be avoided if only those liable to trouble were told so before commencing work. Remember that if you prescribe athletics your prescription can not be carried out on rainy or very cold or muddy days, or in winter. The advantage which athletic has over gymnastic work is, of course, due to the fact that it is done in the open air, and you can secure the good effect of an occasional contact with mother earth, besides the additional influence of the sun, wind, and water. But at least one half of the time it is impossible to take athletic exercise with pleasure or benefit. So, at the same time you give an athletic prescription, instruct your patient to take proper exercise also at home or in a gymnasium, else, if the weather is such as it has been for the last two years, he will be most of the time out of training. Remember that man is a gregarious animal; that exercises which taken alone would be very irksome, if performed in a class are very pleasing. It requires more nerve and perseverance than most men possess to take exercise for which they have no particular liking, the same as they would a dose of medicine. But if they see others doing the same things—if a little emulation is excited—and especially if music, marching, and other attractions are introduced, that which before was disagreeable soon becomes a positive pleasure. It is for this reason that a well-regulated public gymnasium, if easily accessible, is better than a home gymnasium.

Then, again, be careful to instruct your patients what to do immediately after exercise; they are liable to throw themselves on the ground or stand in draughts while still perspiring, and then blame the exercise for the soreness or bronchitis which they experience. I have been a daily, or at least a tri-weekly, visitor at a gymnasium for six years, and during that time have had but one cold. Let them understand that the motion must not cease until they have had a cool bath and a rub with a coarse towel (or the rub alone), and have their clothes on. I have never seen any one catch cold from exercise who faithfully carried out these directions.

II. *Overcoming Deformities.*—The principal deformities we may endeavor to overcome by exercise are the following: Round or drooping shoulders; flat or hollow chest; head too far forward; one-sidedness; deficiencies; spinal curvature.

The general principle to be observed in overcoming deformities by means of exercise is putting the patient in the correct position to overdevelop the muscles which tend to bring the parts into this position, and keep them there. The studying out of just what part needs developing is often very complicated, as in the case of spinal curvature.

In the case of round shoulders the movements to be used are those which tend to develop the interscapular muscles. These may be developed best by carrying the hands from a front to a side, horizontal, either free or against the resistance of pulley weights or dumb-bells.

Sloping or drooping shoulders may be elevated by increasing the size and power of the muscles which raise the shoulders, the scaleni and trapezius principally. The best motion for this is to carry the hands free or with resistance from bells, weights, or rubber straps from a side parallel below to a side parallel above. The same motion which tends to carry the shoulders back also brings out the flat or hollow chest. The systematic protrusion of the chest will also help, and, by contracting the abdominal walls and forcing the contents up into the thorax, as is done when we stand rigidly erect, we may help greatly to bring out the flat or hollow chest.

A very common and very bad deformity is produced when the head is allowed to droop forward. This is generally accompanied by a sinking in of the chest, round shoulders, and a protrusion of the abdomen. The muscles to be strengthened here are the posterior cervical. A very good way to do this is by bending the head forward, grasping the occiput between the clasped hands, then slowly pulling it erect, all the while opposing the action by the hands. If any one does not believe that this motion will make a man hold his head up, try it slowly ten times and then let go; the head will be as erect as the most enthusiastic drill sergeant could desire, and the continuing of the exercise several times daily with an effort to stand erect will certainly overcome this habit. The cure of one-sidedness (and by one-sidedness I mean the opposite of ambidexterity), theoretically is very simple, practically will require an amount of patience which few of us possess. But by using the left hand in every place where it can be substituted for the right, in all the manipulations of the toilet, in cutting food, in playing tennis or fencing, especially when contending with an inferior adversary, very much may be done to make the left hand as strong and dexterous as the right.

To a certain extent parts which are naturally smaller than they should be may be increased by exercise. Of course, every muscle has its limit beyond which it can not be developed; but few of those we may be called on to prescribe for have reached that limit. The only rule is to use sufficiently, but not overuse, the muscles of that part. In this way the arm or forearm, leg or thigh, may be developed and the circumference of the chest increased often in a short space of time. I have frequently seen the circumference of the arm at the biceps increase two inches and the circumference of the chest four inches during one year after ordinary growth had ceased.

In the same way the muscles of the neck may be enlarged and made more beautiful by bending, twisting, and rotating it. Some even allege that a thin-faced man may have his countenance become "plump and pleasing" by the contraction and exercise of the facial muscles. This looks well in theory, but, not having had any experience with the method, I can not say what its results in practice are.

The general subject of spinal curvature is altogether too great to be more than mentioned in a paper like this. But I believe that more may be done toward preventing it and

overcoming it when present by exercise than in any other way.

The most common form of lateral curvature is where there is a double curve, the convexity being toward the right above at about the level of the scapula and toward the left below. This is generally produced by the habit of carrying children on one side only, by overuse of one side, and by sitting with the right side at the desk in school.

There is a great diversity of opinion about the best way of curing it. The way generally adopted now is to exercise the muscles over the convexity, or, placing the patient in a straight position if possible, to give exercise while in that position. Pulley weights are a very valuable adjunct in the treating of this oftentimes very troublesome deformity.

Always in trying to overcome deformities remember what a potent factor the will is, and that, in order to be successful, one must constantly endeavor to have the patient do all he can by his own will. This is especially true in regard to the deformities which can for the moment be greatly improved by muscular action, such as those of the shoulders, chest, and neck. Indeed, I believe that the wonderfully erect carriage of the West Point cadet is due as much to the *esprit de corps* there as to the famous setting-up drill. This drill, however, is admirably adapted to produce and maintain an erect carriage, and I would recommend it to any one who wishes to acquire one. It may be found in Upton's *Military Tactics*.

III. It seems almost like quackery to say that the same measure will either increase or diminish weight. But, as an adjuvant to other measures, I know of nothing better than exercise.

In order to reduce weight it is necessary that heavy and long-continued exercise be taken. In addition, heavy clothing or a sweater should be worn, and then, if water or any other fluid is abstained from and the supply of fluid diminished, it is certain that the weight must come down. The trouble here is that fat men are generally indisposed to exertion and can not confine themselves to this rigid training for any length of time, and it requires the will of an "Iron Chancellor" to keep up the necessary regimen.

To increase weight an opposite course should be taken —only just enough exercise to give a good appetite and digestion and sound sleep; then, if plenty of good, nutritious, and fat-forming food is taken, together with tonics if necessary, we are doing all we can to increase weight.

I have often seen men's weight increase or diminish many pounds as the result of following out these plans. It is easier generally to diminish than increase, if the patient will work hard enough and obey directions implicitly.

IV. It is not certain whether the tendency to organic or hereditary disease may be overcome by exercise in all cases or not. The subject is too great to enter into in a paper of this kind and without a large and long experience in the prescription and effects of exercise. But it seems reasonably certain that in pulmonary diseases, if the lungs are kept thoroughly aerated and expanded daily, there would not be anywhere near as much liability of the tubercle bacillus finding lodgment in some unused spot.

Then the high grade of general health which a proper amount of exercise tends to develop is the best possible safeguard against the encroachment of morbific germs. This is shown well in the case of ordinary colds. I have repeatedly seen people who, before taking exercise regularly, were afflicted with colds nearly all the time, but afterward had a great many fewer or none at all. And right here I should like to mention a little plan to avoid taking cold when exposed to a draught. Many of us are frequently exposed to draughts when we are in company and can not avoid them. If a person in this position would rapidly and strongly contract the large body muscles, or opposite plates of those attached to the limbs, by means of which a great deal of force may be exerted and but little motion caused, he will have no fear of a draught producing a chill. By contracting in this way the muscles which cause adduction of the arms while the arms are at the side, I can in a short time produce a very comfortable state of perspiration, and certainly ward off any bad effects of a draught.

In regard to the effect of exercise on diseases of the heart, I have seen cases which were diagnosticated by several physicians as mitral regurgitant gradually grow less prominent and disappear. I have often seen cases where the heart sound was roughened, accentuated, or indistinct, improve rapidly and acquire a perfect sound when the only change was in taking regular exercise. In the case of hearts, when the only trouble was excessive rapidity, intermittency, or irregularity, I have seen improvement follow very rapidly. And I believe that one of the best prophylactics against the development or extension of almost any hereditary or organic disease is muscular exercise properly taken. And, in conclusion, I should like to say that, in my opinion, the value of exercise is not exceeded by that of any single therapeutic measure. I am certain that all of us have seen patients for whom it would do more than any other thing consistent with their lives and occupations.

And if we were able to intelligently prescribe, and so get all the good possible out of, exercise, I am confident we should be able to do many patients more good than in any other way.

TIC DOULOUREUX

RESULTING FROM AN EXOSTOSIS ON THE SEPTUM NARIUM.*

By E. M. GILLIAM, M. D.,
COLUMBUS, OHIO.

As this is the age of invention, so it is the progressive era of medicine. Investigators of to-day are making strenuous efforts to advance new facts, while teaching is being put on a practical instead of a theoretical basis. This continuous contention for advancement is not confined to any one particular branch, but each has its champions, who are improving on the tenets of their predecessors.

This is evidenced not only in eye, ear, gynæcological, and surgical work, but also in that branch which, but a few years back, was in its incipiency, but has recently been brought forward as dealing with the *fons et origo* of many

---

* Read before the Central Ohio Medical Society.

important neuroses. I refer to rhinology. To such reflex troubles as neuralgia, hemicrania, chorea, epilepsy, neurasthenia, and asthma, which sometimes result from pathological conditions in the nasal cavities, we may give credence, but whether many other diseases of supposed reflex origin can be attributed also to such abnormities is as yet a question *sub judice*, for a true reflex physiology teaches us that three conditions are essential: 1, a sensitive nerve fiber; 2, this must be in connection with a central nervous cell; 3, the latter connected with a motor organ. Flint ascribes to the term reflex any generation of nerve force which occurs as a consequence of an impression received by a nervous center. It is probable that no part of the body is so susceptible to reflex tendencies as the respiratory tract, and one of its most exposed parts is that of the nasal mucous membrane.

This membrane has an exceedingly delicate nerve structure ramifying through it, and abounds in blood-vessels. Without going into the intricate details of the anatomical structure of the turbinated bodies, I shall only call attention to the most salient points which concern us at present.

These bodies, numbering three in each chamber, are covered by mucous membrane, having on its external surface flat epithelium, and the deeper layer forms the periosteum of the turbinated bones. Between these two layers there is abundant lymph tissue, studded with numerous glands whose function is to secrete mucus. The arterial supply is derived principally from the spheno-palatine artery. The capillaries are divided into three sets—one set being distributed to the periosteum, the second to the glands, and the third to the surface. The nerve supply is derived from the olfactory nasal branch of the trigeminus and filaments from Meckel's ganglion.

Hypertrophied turbinated bodies are perhaps the most frequent cause of nasal stenosis. Now this condition may be brought about by continuous irritation of the erectile tissue, causing either a diminution or paresis of the contractile powers, resulting ultimately in an increase of fibrinous material. What is the result? Occlusion or partial stenosis of the chamber, damming up the secretions, producing decomposition, which in turn irritates and perpetuates the low grade of inflammation already existing, by this means adding new material to the hypertrophied state.

This, in connection with a deviated septum or bony growth, may eventually result in a reflex neurosis by the contiguous surfaces encroaching on each other, producing pressure and nerve irritation.

Such conditions are sometimes met with in those persons whose occupation requires them to breathe certain irritants, such as workers in acids, file-works, or places where much dust is continuously circulating. Bony growths are also frequently found in the nasal cavity. The most common is that of the spinous process which arises from the superior maxillary bone, projecting and causing partial occlusion of the inferior meatus.

The septum narium at its junction with the anterior floor often becomes thickened by increase of its cartilaginous tissue and may produce a process of the size of a pea. This condition may arise from a gouty or rheumatic state of the system. The tubercle of Zuckerkandl is sometimes mistaken for an exostosis, as it occasionally attains considerable dimensions. Exostoses may also appear on the septal wall and, in exceptional cases, cause more or less irritative disturbance. In the following case such actually occurred, and, by removal of the cause, resulted in a complete relief if not a permanent cure.

Mr. J. G., aged fifty-six, rugged in appearance, hereditary tendencies and habits good, had for several years past been a great sufferer from tic douloureux. Many physicians were consulted, but only temporary benefit was received. On advice, he repaired to the dentist to have his teeth examined, in hopes of eliciting a cause. Several decayed teeth were extracted and other operations performed, but all in vain; the trouble still persisted. The pain started at the upper lip, darting along the left side of the nose to the forehead.

These pains were paroxysmal and atrocious, during which he would pace the floor, wringing his hands while tears coursed down his cheeks. The attacks followed each other in rapid succession, incapacitating him for business weeks at a time. When they were very severe in character the left side of the face would swell; and as for food, he dare not indulge for fear of aggravating the pain. This condition existed for some time, becoming much worse in damp and cold weather, ameliorating during dry spells.

In the early part of October, 1888, he consulted Dr. D. Tod Gilliam, who advised an operation. A few days after, assisted by the writer, Dr. Gilliam performed stretching of the supra-orbital and infra-orbital nerves. This gave relief until September, 1889, a period of nearly eleven months, when the patient came to the office saying the paroxysms had returned, but not so severely as before. Noting the somewhat stuffed condition of the nose, the thought struck me that perhaps that organ would reveal something that might help us out. On examination, there was found an extensive hypertrophied condition of the inferior turbinated body in the left chamber, and on the septum narium behind the junction of the vomer and triangular cartilage a hard, immovable body, light-pink in color, and bleeding easily when touched with a probe.

This proved to be an exostosis and impinged firmly against the inferior turbinated, entirely occluding the lower channel of the nares. On applying a four-per-cent. solution of cocaine, the membrane covering the inferior turbinated bone retracted slightly, allowing the probe to pass between it and the bony growth, revealing an excoriated surface on the mucous membrane. Stating to him the character of the nasal trouble and the possibility of it being the cause of the neuralgia, I advised as a *dernier ressort* an operation, to which he readily consented.

On September 20th, after cleansing the cavity with Dobell's solution, cotton plugs saturated with a four-per-cent. solution of cocaine were introduced to procure as much dilatation as possible. After inserting a bivalve speculum and thoroughly illuminating by means of condensed light, a sharp-pointed, curved bistoury was used to separate the mucous membrane covering the exostosis. This being done, Bosworth's nasal saw was brought into play and, after much trouble, the growth removed, leaving a slight depression in the septal wall. During the operation the hæmorrhage was profuse, ofttimes obscuring the field completely from view, the cocaine seeming to have no effect in curtailing it. The operation was almost devoid of pain. After cleansing again with Dobell's solution, a tampon of absorbent cotton saturated with cocaine was inserted, which seemed to have the effect of restricting the flow of blood.

The patient returned on the 23d saying his nose felt somewhat freer, and that he had had no recurrence of the pain to speak of since the operation.

After cleansing the wound it was found to be healing kindly, and on the 10th of October it was entirely well. It was next thought best to reduce the inferior turbinated body.

Instead of pursuing the older method of smearing a probe with chromic acid and running it along the elevated surfaces of the mucous membrane, by which means unnecessarily much tissue and glands are destroyed, a more conservative course was resorted to, which consisted in pinning down the mucous membrane to the underlying structures. A slender probe being dipped in mucilage, then into the chromic acid, enough of the crystals will adhere to form a bead on the end of the probe when held over a flame. Now, having the tissues thoroughly contracted by cocaine, the probe is touched only to those parts which by their elevated aspect reveal an abnormal amount of fibrinous deposit. This has the effect of constricting permanently the venous sinuses and arterial channels, cutting off the excessive nutrition to the parts without obliterating or hindering the function of the mucous glands.

These applications were made at intervals of one week until he had had five séances. By this time the membrane was pinned thoroughly down, leaving quite enough space for a free current of air.

From the day of the operation to the present time he has had no recurrence of the trouble, so that, although I am not prepared to state whether the result will be permanent, I am convinced of the nasal trouble being the salient factor in the case.

A CASE OF INVAGINATION OF THE BOWEL.

By M. M. ADAMS, M. D.,
GREENFIELD, IND.

Noble M., eleven years of age, while at play sustained a heavy fall on his back by being tripped backward by a schoolmate. He soon became very sick, and went home complaining of cramp in his stomach and abdominal pains. From September 5 to 15, 1885, I had treated him for an attack of enteritis, and at that time I was apprehensive of obstruction, because of the difficulty experienced in moving his bowels, there being a tenderness and elevation in the right iliac region, but no marked tumor. This, however, passed away after a free movement of the bowels, but every few months I supplied the family with a phial of anodyne and stimulant to relieve sudden and severe attacks of pain in the stomach and bowels, which were attributed to indigestion, relief being obtained by a few doses followed by a cathartic, leaving him very sore for a few days, as in the case of one having had cramp colic. He was a boy of light weight, nervous, and endowed with more than ordinary courage and endurance for one of his years. On December 16, 1889, I was applied to for a remedy for the pain caused by his fall. Relief did not follow, as in former attacks, and at ten o'clock on December 17th I was sent for.

On my arrival I noted the anxious expression of countenance usually observed in cases of wounds of the bowels. He was lying on his right side with knees drawn up, and evincing signs of severe suffering. The history of the fall was detailed to me, and I was further informed that soon after the fall he had had two copious evacuations from the bowels, largely composed of blood. This fact had not been made known even to the boy's mother until the day of my visit. Up to this time I had made no examination, but I at once suspected invagination of the bowel. Placing my hand on his abdomen and moving the palmar surface from the upper to the lower part, I at once located a tumor in the right iliac region, extending well up toward the hypochondrium, thus supporting my suspicion as to the intussusception. He had vomited a green, watery fluid a few times through the night and morning, but there was no fæcal odor. The abdomen was not distended—in fact, it felt flaccid and empty.

I prescribed a sixteenth of a grain of morphine with a quarter of a grain of calomel every hour for a few hours, until nausea ceased, allowing no cold water, but a liberal quantity of hot When I saw him, at 6 P. M., he had become quiet, his stomach retained ingesta, and he was allowed some milk with barley-water. A rectal injection of three pints of hot salt water brought away clotted blood, and the water was stained a cherry-red, as was the next injection, six hours later, but no fæcal matter was discharged.

December 18th, 8 A. M.—No fever; pulse quite regular and 100 in a minute; tongue rather dry, slightly coated, and of a grayish-brown tinge; abdomen very tender over the ascending colon, and tumor very distinct. He craves water often.

19th.—He is growing very restless, requiring anodynes every three or four hours to enable him to be kept in bed. Morphine, one eighth of a grain; atropine, one one hundred and fiftieth of a grain, administered at such intervals.

For the next three days he remained about the same; there was no vomiting, no fever, and the pulse ranged from 100 to 120. He was fed on milk and barley-water, and copious ene-

mata of milk were given every three or four hours. A few times the enemata brought away fæcal matter, which rendered

the case a little more hopeful. The fact of the hæmorrhage being an early symptom rendered it hazardous to use forcible injections.

23d.—Dr. S. M. Martin was called in consultation. The patient's pulse 112 to 120 morning and evening, abdomen greatly

distended, no vomiting. Urine has been passed every four to five hours in fair quantity, but usually when the patient was up to discharge the injected milk.

24th, 8 A. M.—Rested well the first half of the night. At midnight the pain returned with renewed severity. Abdomen more tympanitic. Treatment continued.

25th, 8 A. M.—Quiet and bright. Bowels less tense. At 8 P. M. he became restless, the usual dose not affecting him. Chloroform by inhalation was resorted to to palliate his suffering. At about eleven o'clock stercoraceous vomiting set in.

26th, 8 A. M.—Pulse barely perceptible, surface cool, temperature 97° F. No fæcal matter passed after the last few injections, though they had been used to the full capacity of the colon. Brandy by the rectum was resorted to, with milk every three hours. Aromatic spirits of ammonia and wine were given alternately; morphine and atropine as before. At 2 P. M. Dr. Comstock and Dr. Boots were called to see the case. The patient had but partially rallied from the collapsed condition of the morning. All that had been done was fully indorsed, but no satisfactory conclusion as to the exact diagnosis could be arrived at. All concurred in an unfavorable prognosis and in the opinion that a few hours would end the patient's sufferings. Treatment was continued.

At about 10 o'clock A. M. on the 27th vomiting ceased, and up to January 3, 1890, the patient rested well for several hours at a time, and the injections, which were continued, failed to bring away either blood or fæces. On the 3d, however, vomiting returned at about 6 P. M., and continued for twenty-four hours, when death ensued.

Twelve hours after death a post-mortem was made. Rigor mortis fairly well marked, no post-mortem changes. On opening the abdomen, it was found that the omentum had been nearly all absorbed, only a few floating shreds remaining. The colon was empty, both transverse and descending; the small intestine was distended with gas. The tumor was found to consist of a portion of ileum, several inches of which had passed through the ileo-cæcal valve into the ascending colon. The accompanying illustrations show the coiled condition of the impacted bowel, which was gangrenous. No inflammatory action had been set up except a recent patch in the right hypochondrium, a patch of peritonitis. There was one little ulcer in the jejunum that would admit a darning needle, but it was agglutinated so that no contents of the bowel had escaped. All of the abdominal viscera presented a macerated appearance, and there was a little viscid liquid in the peritoneal sac.

Dr. Martin was called in consultation at about the time the fæces were returning with the injections (December 23d). We were of the opinion at that time that an obstruction existed in the bowels, but could not determine as to its character. We were somewhat confused, too, by the absence of stercoraceous vomiting up to the ninth day, and the (to us) unusually large quantity of blood in the stools and passed in injections under our observation.

Query: Would a physician or surgeon have been justified in making an exploratory incision to ascertain the true condition of the case? Would there have been a reasonable probability of benefiting the patient by an operation under the circumstances?

BLINDNESS
FOLLOWING CEREBRO-SPINAL MENINGITIS,
*WITH RECOVERY AFTER TWO YEARS.**

By WILLIAM L. STOWELL, M. D.

Joseph K., born April 28, 1887. Well until March, 1888; then had an attack of cerebro-spinal meningitis from which he recovered slowly in about six weeks. Before he had entirely recovered it was observed that he was blind. The eyes kept their normal external appearance.

In August, 1888, the boy came under my care for acute lobar pneumonia. He was then blind and had nystagmus of both eyes. Although the temperature reached 105° and the pulse over 200 to the minute, he made a complete recovery from the lung trouble.

In October, 1888, he went through a regular attack of measles.

In February, 1889, his ailment was croup.

He enjoyed good health from that date until March 16, 1890, at which time a cup of hot tea was spilled on his right shoulder and chest. This caused only usual symptoms until three o'clock the next afternoon, when he began to have violent convulsions which continued until nine o'clock. At that time I saw him, and gave chloroform, followed by bromide of potassium and chloral. The convulsions were most marked in the left half of the body.

---

* Read before the Section in Pædiatrics of the New York Academy of Medicine, May 8, 1890, and the patient presented.

The next morning he was found to be paralyzed in the upper and lower extremities of that side, and there was some paresis of the face. The tongue is deviated slightly to the left. Some rigidity followed, but this is gradually disappearing.

To return to the feature of special interest, last summer the child's eyes were examined at the New York Eye and Ear Infirmary, and the diagnosis of atrophy of the optic nerves was made.

This was in accord with my own diagnosis, which had been optic neuritis with atrophy following.

I had regarded the prognosis as very bad indeed. About six months since, the family observed that the child appeared to notice movements and to use the left eye. He now sees quite well with the left eye, but less clearly with the right, in which there is still nystagmus. The optic disc in the left eye is getting to its normal condition. That of the right eye is bluish in tint and the vessels are indistinct in it. Hearing and mental faculties good from time of recovery from the meningitis.

As this is only a clinical report, I will make no further observations on the pathology, etc.

PARANEPHRIC CYSTS.*

By ROBERT ABBE, M. D.

The variety of cystic tumors one may encounter in the abdominal cavity is not great.

Ovarian, parovarian, salpingeal, in the female, and hydatid, pancreatic, distended gall-bladder, and hydronephrotic cysts and pus collections, which are common to both sexes, are about all which one will find. Exceptionally one may meet a cystic tumor that will have an entirely different clinical history and require different treatment. There may be variations of the above, as the cyst of an extra-uterine pregnancy, or one of the class under consideration which heretofore may have been ranked with hydronephrosis of the common type. It is proper that they should be differentiated, clinically and anatomically, and it is with a view to giving a suitable rank to this class that I present the history of two striking cases that were extremely puzzling to me until laparotomy cleared up the nature of both:

Case I. *Large Paranephric Cyst; Exploratory Laparotomy; Incision and Lumbar Drainage; Cholesterin in the Fluid; Recovery.*—A lady of forty-eight years, referred to me from Dr. Pellet, of Hamburg, N. J., was in fair condition when first seen by me on August 12, 1889. She gave no history of special illness except an attack of inflammation of the kidneys lasting two weeks, seventeen years ago. Since that time the functional activity of the kidney has been normal and, as far as she has been aware, nothing unusual has occurred in the appearance of her urine. She had excellent digestion and health. No members of her family ever had tumors of any description. She had seven children in the past twelve years without unusual event. Four years ago she first noticed a swelling of her left side, not hard, and extending from the left loin toward the groin, about as long and as broad as her hand. It was painless and did not seem to grow for two years or more. Her health not being affected, she paid little heed to its presence, though she says she at first consulted Dr. T. G. Thomas, who said it was connected, he thought, with her kidney. As it enlarged it filled the left iliac fossa, encroached on the median line, passed the level of the umbilicus, and grew upward to the ribs. During the past few weeks it has grown much more rapidly, and there has been a dull aching in the back.

Her general health has not deteriorated.

On examination, a large tumor was found to fill the left half of the abdomen, extending across to the opposite iliac fossa. It seemed like a large cyst, constricted somewhat vertically, the median portion dome-shaped, with the navel at the summit.

The tumor filled the left iliac fossa and extended well across into the right. It rose into the left lumbar and hypochondriac region and raised the costal cartilages. A sulcus marked its surface obliquely to the left of the median line, and in this portion was resonance, as of an adherent intestine lying more or less vertically. Elsewhere the tumor was entirely dull on percussion. Auscultation was negative.

Vaginal examination reveals a large patulous cervix, the uterus pushed backward and to the right, and movable independently of the tumor. The latter fills the anterior portion of the pelvis and gives a sense of resistance like a thin-walled cyst. The general appearance was of an ovarian cystoma of large size composed mainly of two principal cysts. The most unaccountable feature was the oblique intestine confined to its surface. This was suspected to be adherent. On account of her history that Dr. Thomas had thought it renal in the early stage, the urine was carefully observed. It was of rather low specific gravity, 1·010; acid; no albumin, and contained a few pus cells and epithelium—not enough to give the slightest suspicion of renal trouble.

On August 14, 1889, I made exploratory median laparotomy.

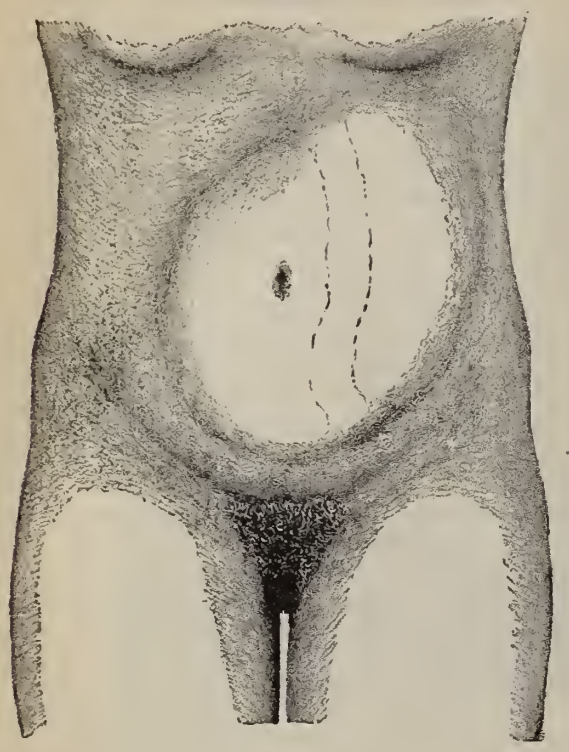
The cyst presented at once in the incision, but differed entirely in appearance from an ovarian cyst. It was invested by an independent loose peritoneal covering, with large vessels traversing it laterally. The presenting adherent intestine was evidently the descending colon raised from its normal bed. The hand, being introduced into the abdomen, was passed over the face of the tumor downward to ascertain its base of origin. It dipped well down into the pelvis, then up behind it freely to the iliolumbar region. Laterally it passed over the smooth surface into a sulcus in the left loin, where the peritonæum reflected on to the tumor at the site of the normal colon, which, however, had been raised far away from its site. On the median side the hand passed around the cyst and returned beneath it to the region of the left kidney. Above, it passed freely over the top, and, reaching the diaphragm, slipped down behind the cyst again to the kidney region.

It was evident then, from all sides, that the tumor originated about the left kidney, and that it had best be opened posteriorly. At the same time, to avoid opening the peritoneal cavity posteriorly, it would be necessary to keep well behind the reflection of lumbar parietal peritonæum. Therefore, while protecting the anterior wound with hot compresses, yet maintaining my hand within to define the peritoneal limits, I made a free lumbar incision as if for colotomy. Rapid evacuation of the contents took place and the cyst collapsed so completely that it was difficult to detect its remaining thin walls by the hand in the abdomen. The colon descended nearly to its normal site.

The most noticeable feature observed was the spread-out kidney. It was not distended, but flattened out against the loin, a crater-like rim being felt on its surface, marking the bed from which the cyst sprung. This was an unmistakable feeling, and was recognized by manipulation through the lumbar as well as the abdominal wound, but best from in front. Some time was taken to discover if possible any connection between the cyst and the pelvis of the kidney, but no sense of distended calyces or funnel-shaped pelvis was present; and it was completely

* Read before the New York Surgical Society, April 23, 1890.

evident that the cyst was independent of the renal pelvis. The anterior wound was closed, and large drainage-tubes introduced through the lumbar wound into the cyst.



The fluid evacuated was as remarkable as the cyst. It measured between ten and twelve pints, was of a pinkish milky color, thin, turbid, and glistening with myriads of cholesterin crystals, which, on standing, deposited to the amount of one fifth the bulk of fluid. The latter was of specific gravity 1·030; contained a large quantity of albumin; microscopically, cholesterin, red blood-cells, a large number, and a trifling number of pus cells; large multinuclear cells, granular round cells, irregular granular masses, and free fat. The patient made a speedy and uninterrupted convalescence. The urine was watched for possible appearance of crystals of cholesterin, which certainly had not appeared before operation. On the day following operation a trace of albumin, a few casts, and a few cholesterin crystals were found, but never afterward. These may readily be explained by the manipulation and probing during the operation, which may easily have lacerated some part of the delicate sac. No urine ever appeared at the lumbar wound.

Under irrigation and drainage the cyst closed, so that in four weeks it would hold but four ounces on distension. In six weeks she was discharged cured, a slight sinus remaining which healed soon after her return home. Since that date, more than six months, the patient has remained perfectly well; has gained thirty pounds in weight, and is actively employed at home.

The second case presented itself three months later.

Case II.—The patient was a young lawyer, aged twenty-three years, of good physique. About the 1st of September he was taken with acute pain in the right hypochondrium, nearly in the region of the gall-bladder, and simultaneously noticed a large swelling at the site of the present tumor. When he was seven years old, and again at fifteen, he remembers to have had similar attacks. He had no fever with this attack and the pain gradually subsided.

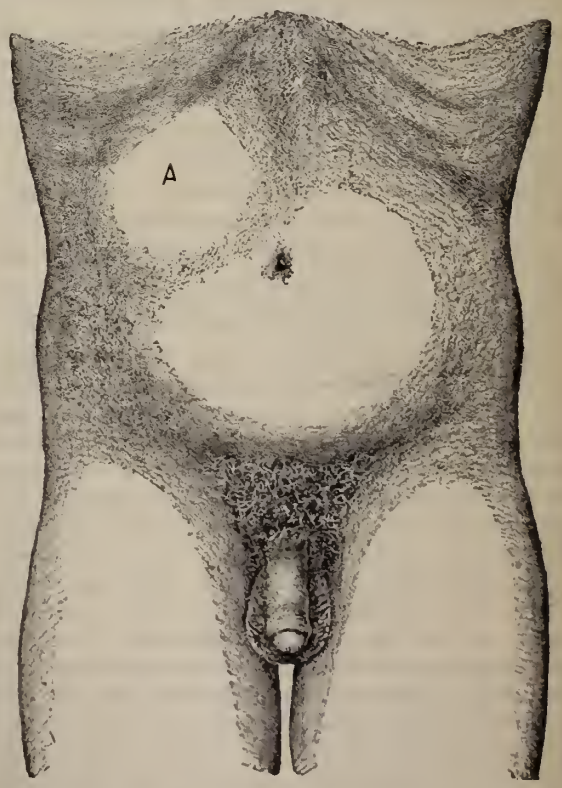
He came under the care of Dr. Kinnicutt and Dr. Draper, with whom I saw him on October 3, 1889.

He seemed to be in good health, excepting that he had a tumor in his side that gave him a little pain.

His normal pulse was 55. Temperature varied from 98° to 99° during two weeks' observation before operation.

Examination showed a globular tumor of the abdomen in the right hypochondriac region, the apex of which lay between the point of the tenth rib and the navel. Palpation showed it to be of very even surface, but more prominent near the point of the tenth rib. It sloped equally in all directions. The loin was also filled by it, so that pressure there raised the summit, but there was no lumbar prominence as there was in front. The liver boundary was raised three quarters of an inch upward. The tumor descended to the level of the navel and extended across the median line. This was discovered rather by palpation than percussion. The colon was pushed downward. There had been no jaundice. The urine was normal. Palpation in different attitudes revealed a lateral movement of the mass of two inches. There was no history of renal colic, with its characteristic pain.

On first examination, my conclusion was that we had to deal with a greatly distended gall-bladder. The following points were a fair guide to this decision: 1. There was an absence of history of renal symptoms. 2. The tumor was evidently a fluid one. 3. The position was considerably higher in the abdomen than the tumor of hydronephrosis. 4. The rotund fullness was most pointed at the apex of the tenth rib and enlarging thence toward the navel. 5. The history of this attack of acute pain, with two preceding ones in former years, was like that of gall-stone impaction. During the two weeks following the patient had no pain; walked about and drove out.



Further examination showed a slight increase in growth across the median line, with less fullness between the navel and the tenth rib. While admitting the possibility of this tumor springing from the kidneys after the fashion of the paranephric cysts, the case previously narrated being fresh in my memory, I was yet more inclined to regard it as occupying the site of the

gall-bladder when distended. It may have had a little more latitude of motion than a gall-bladder of similar size, and possibly could be said to be more full in the lumbar region than that.

The patient was eating and sleeping well. Urine was normal in specific gravity and reaction; had no albumin, or sugar, or abnormal elements on microscopical examination. The presence of the tumor, however, was a menace to him, and therefore, after consultation with Dr. Draper, Dr. Kinnicutt, and Dr. Bull, I operated under ether on October 22, 1889. Incision vertical, as for cholecystotomy. On opening the abdominal cavity, the presenting surface of the tumor was at a glance, as in the former case, seen to be covered by the posterior peritoneal wall of the abdominal cavity, indicated by the appearance of the large vessels traversing it laterally, and by the relatively loose attachment of peritonæum to the tumor. The fingers, passed into the cavity, found the liver free, but pushed upward, and the gall-bladder normal. Passing backward, the possibility of hydatid cyst springing from the liver was excluded. The slope of the tumor in all directions was backward toward the loin. It was free from adhesions on every side.

While conducting these explorations somewhat vigorously, the peritoneal layer investing the tumor was seen to grow rapidly œdematous and puff up so as to fill the incision. Growing rapidly thinner, it burst open in the wound as I attempted to secure it with forceps, and gave exit to a rapid flow of watery, colorless, limpid fluid, sufficient of which was caught for examination. The presenting rent was secured in the wound, and the fluid kept out of the peritoneal cavity. The rent was enlarged, and the flow seen to come from the loose-meshed retroperitoneal tissue. The tumor so rapidly disappeared and its remnant sank back into the loin so quickly that it was difficult to identify any distinct cyst wall among the cellular tissue, and it was deemed unwise to strip up the peritonæum for further exploration. The evacuation being completed, an estimate was made that two pints of fluid had escaped.

A digital examination of the site of the tumor was made. The rent in the peritonæum was two inches above the colon at its hepatic flexure. The liver was entirely uninvolved. The finger passed backward to the aorta and renal vessels, thence downward around the colon and over it to the kidney, whose entire surface was palpated. The lower end was round, smooth, and normal. The rest of its surface was not quite as even as natural, and was spread out into four flattened lobulations. The collapsed tumor sac and adjacent colon fell back so as to cover this area, and no trace of other abnormal condition could be discovered. The posterior rent was therefore stitched to the abdominal incision and the latter closed, except for drainage of the retroperitoneal space, through which the fluid had escaped. My original intention had been to drain posteriorly if I found such a renal cyst, but the bursting of the sac required anterior drainage.

The cyst fluid was of very low specific gravity—1·003. It contained a trace of albumin; no urine salts; no bile salts; no hydatid elements; some chlorides. During evacuation hydatid daughter cysts were watched for but not seen. The diagnosis, therefore, must remain of thin-walled cyst of the surface of the kidney, growing so as to distort the organ by surface pressure.

After operation, free drainage of limpid fluid continued for thirty-six hours, when it rapidly lessened, and his convalescence was uninterrupted. His temperature fell to normal in four or five days. On the fourth day he had considerable albumin appear in his urine, with casts. All disappeared during the four days succeeding, and he was discharged cured during the fourth week.

He has since been carefully examined by Dr. Draper, nearly six months after operation, and he remains free from all signs of trouble.

There seems in the cases given to be evidence that in both we had renal cysts *not* of the usual type of hydronephrosis. The pelves of the kidneys were not the seat of distension, and excepting that, through scratching, a few cholesterin crystals entered the urinary channel a few hours after operation, there was no contamination of the urine by the cyst contents.

The retention cysts of the renal cortex resulting from fibrous change in granular kidney are usually multiple and rarely attain much size. They are bilateral also. Congenital cysts are very rare and due to cystic degeneration of rudimentary tubes. The kidney substance is not left in bulk as in the cases narrated, but attenuated or wanting, and the victims of this deformity are apt to have other deformities and die in infancy. Simple cysts and paranephric cysts, however, are of a class by themselves that directly concern the surgeon by their rarity and importance.

The pathology of their origin is not easily ascertained, as they have usually so attenuated the capsule of the gland and compressed the neighboring cortex as to make it impossible to say whether they sprang from the meshes of the cellular layer beneath the capsule, or from the Malpighian corpuscles, or from their investing cellular layer, or from lymphatic channels. The contents of the cyst give no clew to its origin; they are as various as in cysts elsewhere, varying from clear aqueous contents of very low specific gravity and containing a trace of albumin and salt through every grade of colloid and straw-colored serum. Usually clear, they may have such ingredients as cholesterin, which results from the degeneration of any fatty or cellular substance, or, as seems most probable, of blood. They never have urinous elements in solution.

This uncertainty as to origin entitles such tumors as have been described to the name of paranephric cysts, *resting upon* the kidney, there being no evidence that they arise within the cortex. The recorded cases are not very numerous. They have been known to grow to larger proportions than the first one I have mentioned, and to have been mistaken for ovarian tumors. This seems extremely easy to do if one regards the shape and fluctuation of the tumor and the appearance of the patient. If an early history of growth in the ilio-hypochondriac region can be elicited, or if the physical examination reveals a course of the intestine over its surface, such as the colon took in one case under consideration, it would give a strong point toward differential diagnosis. In my second case the relation of the colon was also of interest, it being pushed down and in front of the tumor. This is perhaps one of the best points for diagnosis that the colon is usually in front of a renal tumor. Yet, as Morris says, an exceptionally large renal tumor will push the colon aside, and, on the other hand, a portion of intestine will occasionally though rarely fasten itself in front of an ovarian cyst.

As regards the second case, which resembled a distended gall-bladder, I may say on reviewing it that the tumor, while not less prominent than a gall-bladder cyst, was perhaps *less pyriform*, *more movable laterally*, and some-

what more easily raised by lumbar pressure than even a large gall-bladder would have been. Its position was too high for the usual hydronephrosis.

The successful treatment of all serous cysts by incision and drainage makes it probable that no other treatment would have been more successful or less dangerous in these cases. The first case of large cyst shows that a lumbar incision without guidance from within would have probably penetrated the peritoneal sac before entering the cyst, on account of the persistent reflection of the peritonæum close to the kidney, in spite of the fact that the colon had been raised to the surface of the cyst. Exploratory aspiration also would have allowed the muddy cholesterin fluid to empty somewhat into the peritonæum if puncture had been made anywhere but close to the kidney.

A CASE OF HEMIPLEGIC EPILEPSY,

PROBABLY DIABETIC, SIMULATING CEREBRAL ABSCESS.*

By ROBERT ABBE, M. D.

The case the history of which I am about to narrate presents features of much interest to the physician as well as the surgeon, and bears directly on diagnosis in cerebral surgical disease.

The patient was an active man of forty-four years and in exceptionally good health until attacked by the grippe on last Christmas. His influenza was of a severe type—general pains, prostration, sore throat, cough. The sore throat seems to have been the worst, and swallowing was difficult. Two or three days later severe pain began in the left ear, and suppurative otitis media was established. The discharge diminished but never ceased. He was unable to resume work, lost flesh and strength. There were no cerebral symptoms, and he was able to be about. A few days after the onset of his trouble—that is, about January 1st—he observed a marked increase in the frequency and quantity of urination, but no examination of it was then made.

In February he noticed a growing difficulty in giving expression to certain words. This and the patient's general condition seemed a little worse on alternate days. He had one or two headaches weekly, mostly left-sided, with tendency to vertigo. Became rather somnolent.

On March 4th he became dizzy, his legs gave way, and he fell while walking in the street. A sensation "like a shock of wind," as he expressed it, seemed to start in the right foot and spread very rapidly over the right leg, arm, and side. The paresis seemed to come on gradually, as he felt less and less able to walk, and finally dropped, not unconscious but unable to walk. .

March 9, 1890.—Admitted to St. Luke's Hospital, under Dr. George L. Peabody's care. Examination showed that the patient had a mitral murmur; no paralyses; no deviation of tongue; no anæsthesia. Pupils reacted to light. Knee-jerk absent. The other reflexes were present, the plantar rather exaggerated. There was a purulent discharge from the left ear, with perforation of the drum. His skin was dry, tongue coated with brown fur, but moist. Pulse, 80; temperature, normal. The patient was somnolent. About an hour after admission he began to have convulsive movements of the right side, beginning in the foot, was given a hypnotic, and slept. The next morning he was able to walk with a limp. After breakfast another convulsion of the right leg, lasting half an hour. There was some paresis of the leg and hyperæsthesia of the right side, passing away quickly. Also a slight transient aphasia. His chief complaint was of general weakness and the discharge from the ear.

The urine was acid. Specific gravity, 1·042. Sugar, thirty-two grains to the ounce. No albumin. No casts. The ear was frequently syringed with boric-acid solution, and he was given bichloride of mercury, gr. $\frac{1}{32}$ t. i. d., with diabetic diet. During the following week his urine increased in quantity from forty to eighty-six ounces, and the sugar diminished to twenty-six grains. There were several times each day attacks of numbness of the right arm and leg, with considerable loss of power. The patient could stand but not walk. He could not grasp with his right hand. There were no optic symptoms. During the attacks there was hesitation in speaking and difficulty in pronouncing some words. The mind was dull, but there was no loss of memory. The attacks lasted from a few seconds to five or ten minutes and went off as suddenly as they came on. There was a vague history of early syphilis, and he was given eight doses daily of iodide of potassium, forty grains each.

On March 14th convulsive movements of the right arm and hand were noticed, and to a much less degree of the right leg and foot. These lasted only a few seconds and were followed by a stupid condition. Aphasia followed each attack.

17th.—At least two attacks daily were associated with convulsive movements of the right hand and arm. Mouth open widely; eyes closed. On coming out of one attack he was unconscious that it had happened. Examined by Dr. M. A. Starr with Dr. Peabody, no retinal changes were present.

20th.—Up to this date he had been having three or more marked epileptic seizures daily, beginning with numbness of the right leg and arm, and succeded by severe spasmodic convulsions limited to these members. It now extended to the same side of the face. His temperature also rose to 101°, having previously been normal, or nearly so. Evidence of mastoid inflammation also developed rapidly, and in twenty-four hours a well-marked suppurative mastoiditis was found, and he was transferred to my care for surgical relief.

His urine still showed no albumin or casts, but sugar, twenty-four grains to the ounce. During the succeeding twenty-four hours six similar epileptic seizures occurred, wholly limited to the right side. He was seen by Dr. Dana, who noted also some anæsthesia, as well as diminished muscular power of the right side. It was thought possible there might be an extension of suppuration by perforation from the mastoid, causing pressure upon the portions of the brain indicated by the parts involved in the seizures—namely, the centers for the leg, arm and face, and for speech. Preparation was made to operate upon the mastoid, and, if indicated, to trephine also over the ascending frontal convolution.

March 21st.—The patient was etherized and the mastoid well excavated of all suppurative tissue. A piece of loose sequestrum was found within the bone. The bone was so far removed as to undermine the dura constituting the floor of the lateral sinus, and still further in a space the size of the finger nail of the roof of the petrous portion. Into these openings the director was passed between bone and dura mater for an inch in different directions, but no intracranial pus was found.

It was thought best to defer further operation.

After this the convulsive twitchings were slight, but recurred every half hour or less all the next day, lasting, however, only a minute. His tongue deviated to the right. His lips were drawn to the right. Between attacks he seemed fairly intelligent, but could not express himself. He would sometimes

* Read before the New York Surgical Society, April 23, 1890.

repeat words suggested correctly after vain attempts to make himself understood.

On the second day after operation the convulsions were more violent though not so frequent, and his general sense was more blunted.

On the third day I felt that the indications were more than ever for irritation of the cortex of the suspected convolution. The wound was in perfect condition, yet the temperature rose on this day to 102°, pulse varying from 72 to 100 at different hours—on the whole, a disproportionately slow one. The convulsions were wholly localized and the aphasia more complete, suggesting a left-side lesion directly related to the left-ear condition.

On March 24th, therefore, I trephined with a one-inch trephine just in front of the lower end of the Rolandic fissure as mapped out for me by Dr. Dana. The dura and brain seemed normal but a little full. Arachnoid fluid normal. A small puncture was made in the pia and a director gently pressed into the presenting convolution for an inch in three directions. Neither suppuration nor tumor was found. The dura was therefore sutured with fine catgut and the wound closed.

The operation had no appreciable effect on the condition of things. The convulsions were repeated every twenty minutes as before, and on the following day became more general, both sides of the body and face participating. His aphasia grew more complete.

On the third day the convulsions abated in frequency; only one occurred in the night and eight in the day. These were general though more marked on the right. He seemed to understand everything that was said and done, but could not make himself understood.

On the fifth day the convulsions came hourly, were more severe and more general. He gave evidence of exhaustion from this cause. His pulse became weaker. Temperature rose to 105·5° just before death, and he died, after a few hours, of coma.

The autopsy was made ten hours after death by Dr. Thacher, and was watched with great interest by Dr. Peabody, Dr. Starr, Dr. Kinnicutt, Dr. Robinson, Dr. Bangs, and others, besides myself. The brain and membranes, as far as gross examination revealed, were in an absolutely normal condition.

No trace of pus was found anywhere, even in the temporal bone. The arteries at the base and throughout the brain were scrutinized and found apparently normal.

Many close sections were made in the region about the Rolandic fissure as well as elsewhere, and a more normal appearing brain it would be difficult to find. The site of puncturing was exactly in the hand and face convolutions, and no harm had come from the use of the director.

(The linear scar in the brain substance is here shown.)

Further examination of the body showed an abdominal adhesion matting together the pancreas, spleen, and transverse colon. The pancreas was atrophied to a fibrous relic about one quarter its normal bulk. No suppurative process could be detected. It was impossible to say whether this was a recent or long-standing lesion.

Further consideration of the history and revelations of the autopsy led to the conviction that the train of remarkably delusive symptoms resulted from the poisoning of his system through the diabetic poison. This suppurative mastoiditis was undoubtedly the determining cause of irritation of the *left* convolutions.

Bibliography.

A. *Reference Hand-book of the Med. Sciences.*

(Dr. Kinnicutt, *Med. Rec.*, New York, vol. xxiv, p. 221.)

1. Facial hemiplegia; the patient died in syncope with sudden hemiplegia of the body.

2. Landesburg mentions a case of paralysis of the abducens.

3. Dementia paralytica, Hamilton, *N. Y. Med. Journ.*, xl, 1–5.

Locomotor ataxia, tabes dorsalis, insanity, and hemiplegia, are all mentioned as occurring in conjunction with diabetes mellitus.

B. *Guy's Hospital Reports*, vol. xliv, 1886-1887, p. 189.

(Pavy, *On Clinical Aspect of Glycosuria. Brit. Med. Journ.*, 1885, ii, p. 1049.)

"Dr. Pavy states that nervous symptoms, especially spinal ones, are very apt to accompany diabetes. He has seen ataxia associated with it in a great many cases, the symptoms coming on either simultaneously or at different times. There may be pains in the limbs, a feeling of heaviness in the feet, darting or lightning pains, hyperæsthesia, deep-seated pain in the bones, and loss of knee-jerks."

Bouchard and Marie and Guignon, in an abstract in *Brit. Med. Journ.*, 1887, i, p. 236, direct special attention to the loss of knee-jerks.

Nervous symptoms occurred in one form or another in seventy-one out of one hundred and sixty-eight cases at Guy's.

A CASE OF REFLEX AMBLYOPIA
CURED BY
SECTION OF THE SUPRA-ORBITAL NERVE.

By JOHN DUNN, M. D.,
RICHMOND, VA.

The patient, a young man, aged nineteen, came under my observation the latter part of October, 1889. He complained of dimness of vision, which, he said, was getting gradually worse, and of a constant pain in both eyes.

In the winter of 1886 the patient, then aged sixteen, was struck in the right eye with a snow-ball. He did not, however, attribute his loss of sight to the blow, as it was some months afterward that the visual trouble began. The pain from the blow had been so severe that for a time nothing except morphine would give him any relief. In the spring of 1887 he suffered much from neuralgia in the neighborhood of both eyes. In June his eyesight began to fail him, though he was able to continue his studies until the following December. From this time until October, 1889, he was under treatment for his eyes, which continued to get steadily worse.

In October, 1889, the following was the condition of the eyes: A spasmodic winking of the lower lid of O. D. is very marked, occurring from twelve to fifteen times a minute. This twitching of the lid began soon after the eye was struck and had never entirely ceased; at times it occurs much more frequently than at others. A strong light, as that from an ophthalmoscope, increases the number of spasms per minute markedly, while "a cold wind will make that eye wink every second in the minute." There was no corresponding movement of the left lower lid. Both eyes show an irritable condition of the conjunctiva, which is in a state of active hyperæmia. A bright light or an attempt to use the accommodation for more than a very short time causes the eyes to fill with tears. Running from the outer margins of both corneæ to the external canthus of the eye were several small blood-vessels, so enlarged and full of blood that one could readily be led to seek for some irritating foreign body in the outer canthal region.

The cornea, aqueous, lens, and vitreous were perfectly clear. Iris normal. Pupil responded most delicately. The tension of

both eyes was rather greater than normal, perhaps T + 1. The anterior chamber shallower than might be expected in a normal eye. The optic discs and retinæ were perfectly normal. Neither veins nor arteries were overfilled. Both eyes were painful at all times. The pain in the right eye had been constantly present for two years, though it had been much worse at some times than at others. So painful was this eye in damp or wet weather that the patient had long since learned to remain indoors "in bad weather." Cold wind also caused the eyes to pain and water. The pain in the right eye had made its appearance some months before that in the left.

The patient complained also of a gray cloud before both eyes, denser before O. D. This cloud made its appearance about a year ago and had been growing denser ever since. This cloud, which appears to be "always floating by," is, like the pain and spasmodic twitching of the right lower lid, subject to variations. At times, while it is scarcely distinguishable, it never entirely disappears, and its general increase in density from month to month is remarked by the patient. It is present before both eyes; denser before the right. In appearance "it is simply a floating gray cloud with its circumference denser than its center." When it first made its appearance, patient thought his glasses were soiled, and endeavored by wiping them to clear away the cloud. At dusk the patient's eyesight is very bad, and at night he can distinguish no one passing him.

The ball of O. D. is very sensitive to pressure, considerably more pain being caused, however, when the ball is pressed upon through the upper than when through the lower lid. O. S. is also sensitive to pressure, though less so than O. D.

Muscular equilibrium undisturbed. Examination for defects of the color sense omitted.

V., O. D. = $\frac{9}{200}$; O. S. = $\frac{1}{10}$. Glasses give no improvement. With both eyes patient can make out Jaeger 1, p. p. = 12 cm.; p. r. = 16 cm. With O. D., Jaeger 3, p. p. = 8 cm.; p. r. = 16 cm. With O. S., Jaeger 1, p. p. = 12 cm.; p. r. = 17 cm. To do this, however, the patient requires the strongest light, and must be allowed to read very slowly. Reading newspaper type for more than a few minutes at a time is impossible.

Under atropine, V. for O. D. = $\frac{9}{200}$; O. S. = $\frac{1}{100}$. Retinoscopy gives H. $\frac{3}{4}$ D., as measure of both eyes. No astigmatism. With + $\frac{3}{4}$ D., V. for O. D. remains $\frac{9}{200}$, while for O. S. it becomes $\frac{1}{10}$. No glass improves beyond this.

Tested with the perimeter, the field of vision for both eyes is found contracted—that for O. D. very much more than that for O. S. (*Vide* Chart 1.) The contraction is concentric.

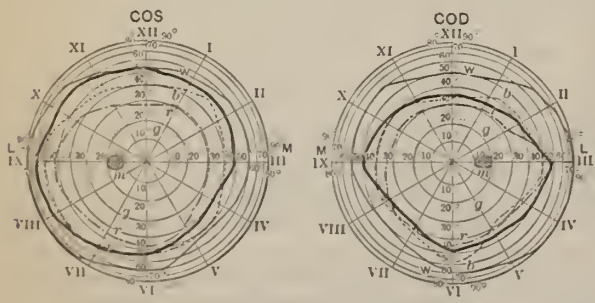


Chart No. 1.—Fields of vision, October 29, 1889.

The general health of the patient had always been good, though he suffered much from "sore throat and catarrh." Examination revealed an enlarged pharyngeal tonsil, superadded to a chronic laryngo pharyngitis resembling much in appearance that found in people of rheumatic tendencies. In addition, there was a moderate hypertrophy of the middle turbinates anteriorly. No posterior turbinate enlargement. Teeth in excellent condition. His whole family, he said, had suffered much from failure of their eyesight, and patient was willing to attribute his loss of sight to an "inherited tendency." The patient says he had syphilis about two years ago. Unfortunately, the physician to whom he had applied when he had his "sores" was not in good standing, and had prescribed a course of patent medicines. From the patient's account of the symptoms, it was extremely doubtful whether he had ever had syphilis, of which there was in October, 1889, not the slightest trace.

The treatment for the eye affection had been very varied. Enucleation had been suggested as a possible resource after the involvement of the second eye.

This was the condition of affairs when the patient presented himself in October, 1889. My diagnosis after a consideration of the symptoms was glaucoma simplex, due to, perhaps, some reflex cause, for I had in my mind at the time Lennox Browne's report of a case of glaucoma cured by eradication of a nasal polyp. There were many symptoms of glaucoma lacking, and the diagnosis was unsatisfactory. To see if in any way syphilis—though no definite ocular lesion could be determined, or even suggested itself—were a factor in the disturbances, the patient was made to undergo for three weeks an active course of mercury and potash. During this time the pharyngeal tonsil was removed and the enlarged middle turbinates were reduced. The eye symptoms in no way improved. The patient then, at my suggestion, visited another oculist. "Tobacco" was suggested "as having something to do with the amblyopia," and a course of outdoor exercise and strychnine advised. Though tobacco amblyopia seemed far less probable

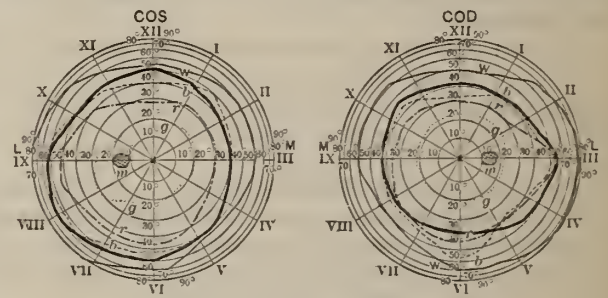

Chart No. 2.—Fields of vision, April 12, 1890.

in view of the symptoms than glaucoma simplex, in deference to the oculist's great reputation no objection was opposed to the treatment. The patient submitted, with the result that on February 7, 1890, vision for O. D. was $\frac{9}{200}$ and for O. S. $\frac{1}{10}$. Absolutely no improvement, while the range of accommodation for reading was considerably reduced. On April 12th the range of accommodation was in O. D. only 2 cm., while for O. S., Jaeger 1, it was also only 2 cm. (p. p., 16 cm.; p. r., 18 cm.). The patient complained greatly of insomnia, which, he said, had troubled him for some months. Examination with the perimeter shows that the fields of vision have changed but little since October. (*Vide* Chart 2.) The weather had been warm, and the twitching of the right lower lid had been consequently less frequent, while, with strong illumination, O. S. could read $\frac{1}{5}$. In passing my finger above the right eye, I noticed that each time it passed over the supra-orbital nerve there was a corresponding twitching of the right lower lid. This fact suggested many possibilities, and an immediate section of the supra-orbital nerve was advised. The patient agreed. The operation was done subcutaneously. The point of a small knife was forced to the bone, external to the nerve, in the supra-orbital notch, and the handle of the knife then depressed. I could feel that the nerve was cut entirely through. The bleeding amounted to nothing. A piece of adhesive plaster was the dressing.

Immediately after the section of the nerve the patient remarked: "For the first time in three years can I wink my right eye without pain." Pressure on the nerve no longer produces spasm of the lower lid.

April 15th.—Wound healed without trouble. Right side of the forehead painful as patient attempts to move skin on his forehead; spasmodic twitching of right lower lid has disappeared. Patient says he feels as if left eye had improved more than right.

V., O. D. = $\frac{12}{200}$; O. S. = $\frac{18}{40}$.

24th.—April 20th was a cold, damp day, and patient suffered much from pain in O. D.

V., O. D. = $\frac{16}{200}$, with + $\frac{3}{4}$ D. = $\frac{18}{200}$; O. S. = $\frac{18}{40}$, with + $\frac{3}{4}$ D., two letters in $\frac{18}{30}$.

Applied constant current, positive pole to back of neck, negative over course of supra-orbital nerve and over upper eyelid of O. D. The application was extremely painful, causing the eye to become bloodshot and to water profusely. The application lasted three minutes. The pain caused by it lasted thirty-six hours, most of which time patient spent in bed.

29th.—V., O. D. = $\frac{18}{100}$; O. S. = $\frac{18}{20}$.

Applied constant current again. Application caused little or no pain.

May 2d.—V., O. D. = $\frac{18}{40}$; O. S., $\frac{18}{15}$.

Field of vision of O. D. is still slightly contracted, although less than that of O. S. was originally. Field of O. S. has become normal. (*Vide* Chart No. 3.) Current again applied for five minutes.

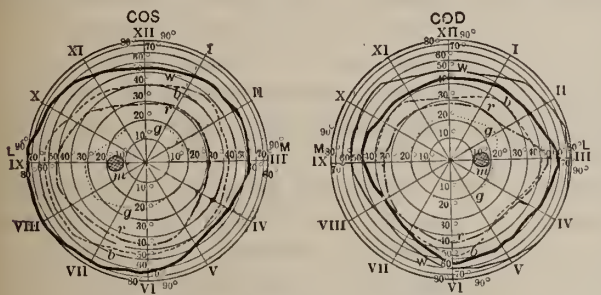

CHART No. 3.—Fields of vision, May 3, 1890.

8th.—V., O. D. = $\frac{18}{15}$; O. S. = $\frac{18}{15}$.

July 16th.—No return of any symptom of reflex trouble.

Thus, in less than four weeks after section of the supra-orbital nerve the vision of O. D. had increased from $\frac{9}{200}$ to $\frac{18}{15}$, while that of O. S. from $\frac{18}{50}$ to $\frac{18}{15}$. The pain has entirely disappeared from both eyes. Both fields of vision are normal. The cloud before the eyes was seen once or twice soon after the operation, but has now disappeared. There is now no longer a twitching of the right lower lid. The conjunctivæ have lost their hyperæmic condition, and the irritated appearance of the vessels running from the outer canthus to the cornea has disappeared. The patient has got his books out again, and, on May 7th, read two hours without fatigue to his eyes. The neuralgia has disappeared, and with it the patient's inability to sleep. In short, the cure has been perfect.

Remarks.—This case has been reported thus at length because of its completeness; because, as a case of reflex amblyopia, it leaves no doubt as to its origin; and, further, because it shows how perfect may be the return *ad integrum* of the functions of an organ which for years has been disabled through a reflex agency. Moreover, it adds one more to the many pleas that a careful search should always be made for a reflex cause in troubles which have no definite pathological lesion. Reference has been made to the treatment of the case other than the section of the supra-orbital nerve, because it is of interest in showing the uselessness of general remedies in reflex troubles whose source is a definite anatomical lesion. As in all reflex troubles, this case presents many points of interest. The pathogeny of the amblyopia? The case adds little to any of the hypotheses that have been formed to settle this question. The direct cause that kept up the reflex symptoms? It seems more than probable that the blow so injured the sheath of the supra-orbital nerve that an adhesion formed between the sheath and the adjacent tissues. This adhesion, then, could have become the source of continuous trouble, since each movement of the upper lid, as in winking, or each contraction of the skin over the forehead, as in frowning, would have dragged upon the nerve by means of the adhesion. Or continuous pressure may have been exerted upon the nerve through cicatricial contraction left as the result of a perineuritic inflammation set up by the blow. In either case the question arises whether the cure obtained through simple section of the nerve at the seat of adhesion or contraction will be permanent. The influence of wind and damp weather in increasing the pain in the eye seem to point rather to a subacute inflammation of the nerve itself. If so, then had the section of the nerve or the application of the electric current the greater share in procuring a cure which may be looked upon as permanent? The order in which the eye symptoms developed, the fact that vision did not begin to fail for six months after the blow was given, the gradual but sure increase in the symptoms, the almost complete abolition of the range of accommodation for small objects—these all furnish food for reflection, and seem in more than a vague way to point us to nerve exhaustion as the prime factor in the pathogeny of reflex troubles, nerve exhaustion called forth by continuous excessive energy due to a continuous point of irritation in a nerve filament closely allied to the organ in which the reflex symptoms show themselves. The question, too, whether, as a result of this blow, there would have been in course of time a real degeneration of the organ of sight comes up. At all events, after three years and a half have elapsed, during the whole of which time the reflex cause had been at work, the removal of the cause does away almost immediately with the effects.

CONGENITAL STENOSIS OF THE DUODENUM.

*HÆMATEMESIS; DEATH ON THE FIFTH DAY; AUTOPSY.**

BY J. H. EMERSON, M. D.

N. B., male, the fifth child of healthy parents, was born on April 24th after a normal and easy labor of about fifteen hours. Weight, eight pounds and a half; circulation perfect. Appeared well nourished and well developed in every respect. When about thirty-three hours old the child suddenly and without any apparent cause spat up or regurgitated about half an ounce or more of rather dark blood, partly mixed with mucus. This effort involved some choking, and was followed by some

* Read before the Section in Pædiatrics of the New York Academy of Medicine, May 8, 1890.

blueness and coldness of the extremities. The same thing was repeated four or five hours later, but with less effort and disturbance, and after this recurred at intervals and in varying but not large amount for eight or nine hours longer. The nurse reported that there had been a trace of a reddish stain in the mucus from the mouth since birth. The bowels had moved freely before the blood-spitting began—a dark, tarry stool. The child evinced no desire for food, and would make no effort to take the breast. Gave no sign of suffering except when raising the blood from the throat, which act was accompanied by some gagging, but hardly a vomiting effort. Some blood also escaped through the nostrils. No cough. No fever. No disturbance of respiration. Examination of the surface of the body and of the month and fauces revealed nothing abnormal. The attempt was made to give one drop of spirits of turpentine in water, also subsequently a little milk and water and some minute scraps of ice, but it is doubtful if anything was swallowed at this time, and these attempts only led to increased regurgitation and bleeding. Another stool at this time contained only meconium; no trace of altered blood. When the child was about forty-six hours old Dr. A. Jacobi saw him in consultation, and made a thorough examination without being able to satisfy himself as to the source of the hæmorrhage, although we concluded that the symptoms pointed to its coming from somewhere low in the pharynx. A weak solution of alum and potassium chlorate was prescribed, to be applied in the pharynx hourly with a camel's-hair brush. From about this time no more red blood was ejected, although there was a slight brownish stain to the mucus from the mouth. During the succeeding thirty-six hours the child received small quantities of milk and water, with a few drops of brandy, also some breast milk from a spoon, but would not nurse, although he swallowed better. At the expiration of this time—viz., when about three days and a half old—he vomited a large quantity of dark-brown watery and grumous fluid, which also poured through the nostrils, and a similar discharge took place now and then in greater or less quantity, and not always with an effort of vomiting, until his death. Some of this material, scraped from the napkin and examined with the microscope, appeared to be of an oily character, contained some colostrum corpuscles, and also altered blood-corpuscles. The discharges from the bowels had the same character as the earlier ones, and contained no trace of sweet-oil, of which a teaspoonful was twice administered by the mouth. The last evacuation, only about three hours before death, was stained with bile. The child died when four days and ten hours old, emaciated, but not extremely exsanguinated.

The following is the report of the autopsy by Dr. W. B. James:

N. B., aged four days, male, died on April 28th, P. M.

Autopsy, April 29, 1890, 1.30 P. M.

Body well nourished. Length, 48 ctm.

Heart: Foramen ovale patent, 0·1 ctm.; otherwise normal.

Lungs normal.

Peritonæum normal.

Stomach is markedly dilated. From cardiac orifice to pylorus, measured on greater curvature, is 17 ctm. Pyloric orifice dilated, 2 ctm. diameter. Duodenum markedly distended, 3 ctm. in diameter, the distention reaching to a point immediately above the orifice of the common bile duct, at this point the lumen of the duodenum terminating abruptly. Fluid can not be forced below this point from the stomach, nor can air be forced from the intestine upward into the stomach.

A probe, medium-sized, can be passed through the constriction, which appears to be not complete.

Stomach contains a large amount of brownish-black, fluid, somewhat grumous material.

Small intestine, below the above-mentioned constriction, normal.

Large intestines normal.

Œsophagus: Immediately above cardiac orifice is a firm, dark-red, oblong thrombus, 2·5 ctm. in length, firmly attached to posterior wall of œsophagus.

Upper part of œsophagus and pharynx normal. Liver normal. Kidneys normal. Bladder normal.

Microscopic examination of the above-mentioned thrombus, with œsophagus wall, showed erosion of the mucous membrane immediately beneath the thrombus. The exact nature of the process giving rise to the bleeding could not be made out.

It should also be noted that at the autopsy the intestine below the constriction in the duodenum was found almost entirely empty, containing but a very little dark meconium in the lower portion, while its upper part was stained yellow with bile for a few inches.

I would call your attention to a few points of special interest.

Both the abnormal conditions here presented are of very rare occurrence. As to the lesion of the œsophagus, I have not succeeded in finding an account of any such condition, hæmorrhage from that canal being attributable either to traumatism, to heterologous deposits, or to antecedent disease, either constitutional or local, none of which were present in this case. The one most nearly resembling it is reported by Henoch (*Lectures on Children's Diseases*, vol. i, transl. from 4th German edition by John Thomson, London, New Sydenham Society, 1889, p. 68). He says: "The following case stands alone. A child of five days, admitted October 1, 1881. Since the third day of life, repeated vomiting of blood and black bloody stools. The child sickly, shriveled, anæmic; extremities cold; anal aperture covered with bloody fæces. Pulse imperceptible; temperature, 87·8° F. Takes no nourishment. Death that evening. Post-mortem: General anæmia; spleen normal. Immediately over the cardia, a ring of ulceration, an inch and five eighths long, surrounding the whole œsophagus. The submucosa remained free; it was swollen and infiltrated with grayish-white matter. The ulcer sharply defined above; otherwise everything normal. We were unable to throw any light upon the origin and nature of this œsophageal ulcer."

The occlusion of the duodenum was not structurally absolute, although the canal was impervious to both air and fluid. Its condition resembled a gathering together of all the tissues of the gut at that point, much as a bag is drawn together by a string. In regard to the pylorus, Ziegler says (*Text-book of Pathological Anatomy and Pathogenesis*, transl. by Donald MacAlister, New York, 1887, p. 617): "Complete atresia of the pylorus is very rare, but stenosis or abnormal contraction is more frequent (R. Maier)." Nor does the state of things here seem identical with that referred to by Widerhofer (Gerhardt, *Kinderkrankheiten*, vol. iv, part 2, p. 353), where he says that the lumen of the stomach or intestine may be narrowed or obliterated by partitions, the origin of which is not well understood.

Another question which naturally arises is whether there was any causative relation between the hæmorrhage and the coexisting stenosis of the duodenum. In other

words, is it probable that the effort of vomiting caused a lesion of the mucous membrane of the œsophagus, and so hæmorrhage, in analogy with the case of rupture of the œsophagus of the Dutch admiral, as reported by Boerhaave? The history of the case would negative this theory, for the vomiting was never violent, the raising of red blood was the earliest symptom noted, and it took place before any kind of food or drink had been taken into the stomach.

With reference to diagnosis, it may be said that the non-appearance of blood in the evacuations from the bowels, while it distinguished this case from those of melæna, might have given a hint of the possible existence of an occlusion of some part of the alimentary canal, especially when coupled with the fact that the sweet-oil swallowed also failed to show itself in the dejecta.

NOTE ON CHLORALAMIDE.

By WARREN B. CHAPIN, A. M., M. D.

The cases in which I have used chloralamide have been mostly those of insomnia of a very persistent character, in some of which all other hypnotics had failed. Although my experience with the drug has been confined mostly to one class of cases—those of insomnia depending on some nervous affection—I have seen enough of its action to convince me that not only does it fail to possess all the virtues attributed to it, but, owing to its uncertain action and the many unpleasant symptoms which it produces, it is inferior to most of the other new hypnotics.

It is maintained that chloralamide has no effect on the respiration or circulation, and can be given in cardiac cases almost with impunity. In doses under three grammes I believe chloralamide to be harmless; but when given in larger doses it will produce effects on the circulatory and respiratory systems that are ominous of what may happen if it is not used with caution. In one instance, two hours after having administered a dose of three grammes to a robust patient, I was sent for by the family, as the patient was "acting queerly." I found her sleeping very heavily, could be aroused with difficulty, respirations labored and 124, and with a pulse of 105. In larger doses I have seen much more pronounced effects, and I would certainly be very cautious in giving this drug in cardiac cases.

Its action as a hypnotic is very uncertain, taking effect in some cases in a very few minutes, while in others its action is delayed for several hours, or else has no effect at all. Sulphonal, to which it is claimed to be superior, is uncertain in its action, but can usually be relied on in certain cases, while chloralamide can not be depended upon to act twice alike on the same patient. In one patient it produced no effect except headache, nausea and vomiting, and great restlessness for eight hours, when the patient fell into a heavy sleep which lasted for twelve hours. On the following day at 5 P. M. I gave the patient, under like conditions, the same dose as on the preceding day; in half an hour she was asleep, and slept for only two hours. Repeated doses had no effect, but a moderate dose of chloral was successful. In some cases it appears to be accumulative, especially if given in its undissolved form, and I have known a second dose to have such a depressing effect on the heart as to render stimulants necessary. If four grammes fail to produce sleep, it is useless to repeat the dose.

Although in some cases it causes a refreshing sleep, with no unpleasant after-effects, yet just as often does it cause headache, which is sometimes very distressing, nausea, great restlessness, or depression. I find these unpleasant symptoms almost invariably occur when its administration fails to produce sleep. A feeling of exhilaration lasting for an hour or two often occurs after taking this drug. A patient told me it always made her feel as though she had taken a pint of champagne; afterward she would become restless, then depressed, but it would never make her sleep.

In other hands chloralamide may prove all that is claimed for it, but after giving it a fair trial I have ceased to use it in my practice.

114 West One Hundred and Fourth Street.

A PECULIAR GROWTH OF HAIR ON THE FACE.

By RICHARD B. FAULKNER, M. D.,
ALLEGHENY, PA.

Unable to find another instance of the growth of hair from a cicatrix, the following is therefore presented as one of interest:

Miss L., aged twenty, received a burn on the left cheek from a cooking-stove when a child. The skin was blistered, of course, by the burning. The scar which resulted is oval in appearance, half an inch wide by an inch and a half in length, very perceptibly elevated, and of a dense fibrous consistence throughout the entire thickness of the derma.

Burns commonly destroy the hair follicles; but in this case a growth of hair appeared upon the scar. A brown pigmentary deposit also occurred. Most of the hair was jet black, and much of it an inch and more in length. The lady is a brunette, a school-teacher. At least twelve hundred hairs were growing from the scar when she applied to me. She is not of a hairy nature.

I removed the entire growth of hair with the electric needle. There is no sign of its reappearance. The pigmentary deposit is becoming fainter; the cartilage-like hardness is giving place to a softer feeling. Much down still covers the cicatrix, but I have consoled the lady with the statement that when the hardness is removed and the pigment entirely gone, the unusual quantity of down will likely cease to annoy her.

Case second is that of a lady sixty-five years of age, addicted to the use of a caustic depilatory for twenty years, which had so irritated the skin as to cause trifacial neuralgia. The skin had become so irritable that the application of water was almost unendurable.

She had a beard and mustache of rather manly proportions. The hair shafts were very thick, and the roots long and strong. The depilatory seemed to me to be a wonderful stimulant in producing the strong, healthy roots. I immediately stopped the use of the depilatory, and ordered oxide-of-zinc ointment every night and morning. I removed from her face *four thousand hairs*. They show no tendency to return. The neuralgia is cured by the measures noted.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, AUGUST 9, 1890.

THE TENTH INTERNATIONAL MEDICAL CONGRESS.

From the dispatches thus far received from Berlin it is safe to infer that the Congress is sitting under conditions that have never been surpassed as regards satisfactory work. The attendance is very large, notably large from North America, and the organization of the Congress at large and of the several sections is such as to impart the utmost weight to the proceedings. The latter fact is due to the good sense displayed by the organizing committee; the former has doubtless been decidedly promoted by the plan adopted in most countries of establishing a national committee (*Landes-Comité*). The United States and Canada joined in the formation of such a committee consisting of Dr. Abraham Jacobi (chairman), Dr. William H. Draper, and Dr. William T. Lusk, of New York; Dr. William Pepper, of Philadelphia; Dr. Reginald H. Fitz, of Boston; Dr. William Osler, of Baltimore; Dr. Samuel C. Busey, of Washington; Dr. F. Peyre Porcher, of Charleston; Dr. Henry Hun, of Albany; and Dr. J. Stewart, of Montreal. The United Kingdom had a committee consisting of three sections, sitting respectively in London, Edinburgh, and Dublin, presided over by Sir James Paget, Dr. Grainger Stewart, and Sir William Stokes. The other countries that adopted this plan, together with the chairmen of the committees, as stated in a recent issue of the *Prager medicinische Wochenschrift*, are: Belgium, Dr. Thiry, of Brussels; Denmark, Dr. C. Lange, of Copenhagen; Italy, Dr. Mosso, of Turin; Mexico, Dr. Lavista, of Mexico; the Netherlands, Dr. B. J. Stokvis, of Amsterdam; Norway, Dr. S. Laache, of Christiania; Austria-Hungary, Dr. Theodore Meynert, of Vienna; Russia, Dr. W. Paschutin, of St. Petersburg; Sweden, Dr. Holmgren, of Upsala; Switzerland, Dr. Kocher, of Bern; and Spain, Dr. Basilio San Martin, of Madrid.

It will be noted that France does not figure in this list. At one time it looked as if the animosity engendered by the Franco-Prussian War would lead the French to hold aloof from the Congress almost altogether, and more recently certain bygone expressions used by Virchow, the president of the Congress, were brought forward by men who might have been engaged in better business, to give our French brethren the impression that they would not be welcome at Berlin; but the best of the French medical journals have most commendably deprecated and sought to counteract this mischievous course, and Virchow has himself explained that one of the passages quoted from his writings ought not to be irritating when taken with the context. This being the case, there seems reason to expect that the final reports will show that many of the physicians of France have entered frankly into the work of the Congress.

In addition to the good accomplished by the national committees mentioned, we must allude to the aid that has undoubtedly been rendered to visitors unaccustomed to German ways by a committee of foreign physicians sojourning in Germany for purposes of study. Moreover, the comfort of lady visitors has doubtless been highly promoted by a committee consisting of Berlin physicians' wives. The number of sections has been increased from eighteen to twenty by the establishment of a Section in Orthopædic Surgery and a Section in Railway Hygiene. All things considered, the Berlin Congress seems likely to go on record as in no wise behind previous meetings, whether for the value of the work done or for the good feeling manifested by those engaged in it.

THE ÆTIOLOGICAL CLASSIFICATION OF MENTAL DISEASES.

In the July number of the *American Journal of Insanity* there is an interesting article, entitled Is Puerperal Insanity a Distinct Clinical Form? by Dr. W. L. Worcester, of the State Lunatic Asylum at Little Rock, Arkansas. The question under discussion by the author is as to whether or not puerperal insanity presents a clinical picture by which, without a knowledge of the history of the case, it can be distinguished from insanity unconnected with childbearing. He gives the histories of eight cases presenting a great variety of symptoms, such as excitement and depression, delusions, illusions, and hallucinations, suicidal and violent impulses, mental confusion, and catalepsy; but it is not clear to him that there was any one symptom common to all the cases, although mental confusion in greater or lesser degree was present in most of them and perhaps in all those reported, for he calls to mind an instance that occurred under his observation in the Michigan Asylum in which the patient seemed very clear-headed, and "certainly manifested great ingenuity and judgment of a certain sort in mischief."

Assuming a maniacal onset and mental confusion as invariable characteristics of puerperal insanity, instead of being merely its most usual manifestations, would that, Dr. Worcester asks, be sufficient to warrant its separation as a distinct disease? His own observations would lead him to answer this question in the negative, for the reason that similar cases are not at all uncommon in men and in non-puerperal women. He has treated a number of patients, both male and female, whose symptoms, so far as he has been able to judge, resembled those of the cases of puerperal insanity recorded in his article quite as much as they resembled those of the others; and their cases, he thinks, apart from ætiological considerations, were as much entitled to be classed with the puerperal cases as the latter were to be classed together. Finally, he has not been able to discover anything in the symptoms, whether considered separately or collectively, that would enable him to say with confidence, in the absence of a history of the case or of physical evidences of recent confinement, that the case of a given patient was one of puerperal insanity.

By implication Dr. Worcester's article tells against the util-

ity of the ætiological classification of mental diseases in general, especially those imputed to masturbation and to the menopause. Not a few, he remarks, are skeptical as to the value of any system of classification, but unsystematized knowledge, he goes on to say, is a constant irritation to the scientific mind and a hindrance to progress, and probably the worst classification that was ever devised is better than none at all.

MINOR PARAGRAPHS.

THE ELECTRICAL EXECUTION.

On Wednesday, the 6th inst., the first judicial execution by electricity took place in Auburn Prison. The procedure resulted in the death of the criminal, but that, so far as we are aware, is the result of the method heretofore in use, and, judging from the press accounts, we see no reason why the new plan should be preferred to the time-honored hanging. The current is said to have been applied two or three times, but probably the repetition was unnecessary. Undoubtedly, as is alleged, the man's consciousness was abolished instantly, and the subsequent twitchings and respiratory efforts were in no wise manifestations of suffering; but the same may be said of a well-conducted execution by hanging. As for the element of sensationalism, it certainly was not avoided in this case. That the method of execution was a merciful one is hardly credible, for it is not the death itself, but the elaborate preparation for it that must be agonizing. Public opinion, we think, will hardly permit another criminal to be executed in this manner.

FOLLICULAR DERMATITIS IN COTTON-SPINNERS.

Dr. H. Leloir, of Lille, has observed a form of follicular and circumfollicular inflammation to be very frequent in male cotton-spinners, and has contributed an account of his observations to the *Annales de dermatologie et de syphiligraphie.* It appears from an abstract of the article given in the *Deutsche Medizinal-Zeitung* that the affection is confined chiefly to the front of the thigh, and is attributed to the action of the highly irritating mineral oils used in freeing the cotton fiber from grease. The workmen wipe their greasy hands on their trousers, which soon become saturated with the oil. The trouble may be prevented by using special trousers while at work and having them thoroughly cleansed at frequent intervals.

MINERS' NYSTAGMUS AND THE SAFETY-LAMP.

Attention having lately been called in the *Engineer* to a belief prevalent among miners to the effect that the safety-lamp is injurious to the eyes, the *British Medical Journal* remarks that nystagmus is the only affection of the eyes to which miners are specially liable, and shows that miners' nystagmus is not caused by the safety-lamp, but by the oblique upward direction in which the miner is obliged to hold his eyes as he lies on his side in the operation known as "holing," *i. e.*, undermining a block of coal. Nystagmus occurs only in mines where "holing" is practiced, and there it is observed whether the safety-lamp is used or not.

SECRECY IN LYING-IN HOSPITALS.

Last week we expressed the hope of seeing institutions established here for enabling women pregnant out of wedlock to be assured of decent support and secrecy until they were relieved of their embarrassment by the birth of a full-time child and recovery from the disabilities of the lying-in period. This we said in the interest of the restriction of criminal abortion. In the course of an essay on the proper measures for remedying the depopulation of France, an abstract of which appears in a recent number of the *Union médicale*, M. Lagneau advocates the establishment of such institutions, and alludes to their existence in Vienna. The officers and employees are sworn to secrecy, and there a woman may be delivered and leave her child behind her when she is ready to be discharged, without her identity being made known.

THE TERM "HEART-FAILURE."

In the *Medical News* Dr. Frank W. Thomas, of Germantown, Pa., relates a case of death intra partum after a rather copious uterine hæmorrhage, which, however, can not have been the cause of death, for reasons given. Only trifling lesions were found post mortem, and the author infers that death was owing simply to failure of the heart's action. In spite, therefore, of the fact that, of late, "registry bureaus, coroners' clerks, and closet pathologists" have refused to accept "heart-failure" as a cause of death, he argues in favor of the term as expressive of what really takes place in certain cases.

EARLY MATERNITY.

Dr. Barton Cooke Hirst, professor of obstetrics in the University of Pennsylvania, contributes a short article to the August number of the *University Medical Magazine* which goes far to show that, from the point of view of the mother's health, precocious maternity does not involve the evils that are usually ascribed to it. He gives brief notes of the cases of twenty girls who were delivered at ages varying from fourteen to sixteen years in the Maternity Hospital, four of them under his own observation. In each of the four cases under his own care the labor was easy and uncomplicated, the infant was well developed, and the mother's supply of milk was ample; and he infers from the absence of any record to the contrary that the sixteen others were normal also.

BROMOFORM IN WHOOPING-COUGH.

The *Lancet* cites the experience of Dr. Hugo Löwenthal, of Berlin, in the treatment of whooping-cough with bromoform in doses of from two to five drops three or four times a day. The dose is simply dropped into a teaspoonful of water, in which it floats in the form of a bead. Generally an amelioration of all the symptoms was produced promptly. In a very few cases sleepiness and lassitude were produced, and in one instance a semi-comatose state was the result, but this yielded readily to subcutaneous injections of ether, and, after the resolution of an intercurrent pneumonia, the use of bromoform was resumed.

A FRENCH STUDENT ON GERMAN STUDENTS.

A French student's impressions of German university life are given in brief in the *Lyon médical.* One reaches Germany, he says, with the idea that the studies there are very hard, and that the German students do more work than the French students; but one presently dismisses this idea, and gets the notion that the German students hardly work at all. On further acquaintance with them, however, it appears that in a German university, as in any other, there are those who work little and those who work much, the former masking the latter because more is seen of them.

THE INDORSEMENT OF FOREIGN DIPLOMAS.

We were in error in our answer to correspondent No. 327 in last week's issue. The new law went into effect on the 24th of June, and by its provisions foreign diplomas held by persons not previously licensed in the State of New York must be indorsed by the Board of Regents of the University, on the recommendation of a legally constituted board of examiners.

THE PRIMARY SYNCOPE OF CHLOROFORM ANÆSTHESIA.

According to an abstract of a recent discussion of the dangers of chloroform anæsthetization, before the French Academy of Medicine, published in the *Province médicale*, M. A. Guérin imputed the syncope that sometimes proves fatal early in the administration of the anæsthetic to the irritant action of its vapor on the pituitary nerves. To prevent it, he recommended forcible closure of the nostrils so that the patient would breathe through the mouth only.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 5, 1890:

DISEASES.	Week ending July 29.		Week ending Aug. 5.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	34	8	35	7
Scarlet fever	28	6	49	6
Cerebro-spinal meningitis	5	4	6	5
Measles	156	8	171	13
Diphtheria	75	31	69	22
Varicella	3	0	0	0
Leprosy	1	0	0	0

The Medical Society of Virginia will hold its twenty-first annual meeting at Rockbridge Alum Springs, beginning on September 2d. An address to the public and the profession will be given by Dr. John S. Apperson, of Marion. On the morning of the second day the president, Dr. Oscar Wiley, will deliver his annual address.

Immediately after the president's address and after its recommendations have been disposed of, the subject for general discussion—The Treatment of Summer Diarrhœa of Children—will be called. The discussion will be opened by a paper by the appointed leader, Dr. C. T. Lewis, of Clifton Forge. Dr. John N. Upshur, of Richmond, will follow with a paper having the same title.

Reports on advances in the eight departments of the medical sciences will be called for in the following order, and continued as the order of business through Thursday until completed: Anatomy and physiology, by Dr. H. H. Levy, of Richmond. Chemistry, pharmacy, materia medica, and therapeutics, by Dr. Henry V. Gray, of Roanoke. Obstetrics and diseases of women and children, by honorary fellow Dr. J. Edgar Chancellor, of the University of Virginia. In this section the following paper will be read: What class of cases of pelvic disease require operation? by Dr. I. S. Stone, of Lincoln. Practice of medicine, by Dr. W. H. Bramblett, of Pulaski City. In this section the following paper will be read: Suppurative diseases of the kidneys—their diagnosis and treatment, by Dr. Edward McGuire, of Richmond. Surgery, by Dr. William L. Robinson, of Danville, who will limit his report to diseases and injuries of the intestines—their surgical treatment, with pathological specimens from experimental work. In this section the following papers will be read: Permanent drainage of the bladder by means of a special cannula introduced above the pubes, by Dr. G. B. Johnston, of Richmond; the present position of abdominal surgery in America, by Dr. Joseph Price, of Philadelphia; the value of early exploratory incision as an aid in the diagnosis of surgical diseases of the abdominal cavity, by Dr. Edward Ricketts, of Cincinnati; subject not definitely stated, by honorary fellow Dr. Hunter McGuire, of Richmond; hip-joint disease, with description of an original splint therefor, by invited guest, and delegate from the New York State Medical Society, Dr. A. M. Phelps, of New York; treatment of appendicitis, by Dr. Joseph Hoffman, of Philadelphia. Ophthalmology, otology, and laryngology, by Dr. Robert L. Randolph, of Baltimore. In this section the following papers will be read: Importance of nasal surgery and nasal therapeutics in the treatment of aural catarrh, by Dr. Joseph A. White, of Richmond; a plea for early operation in cataract and strabismus in children, by Dr. Charles M. Shields, of Richmond; boils in the ear, by Dr. John Herbert Claiborne, Jr., of New York; the modern treatment of strabismus, by Dr. Alexander Duane, of Norfolk; title not definitely decided, by Dr. Laurence Turnbull, of Philadelphia; relations of refractive errors and muscular defects in asthenopia, ocular headache, etc., by Dr. Joseph A. White, of Richmond. Neurology and psychology, Dr. M. D. Hoge, Jr., of Richmond. Hygiene and public health, by Dr. I. R. Godwin, of Fincastle.

The American Dermatological Association will hold its fourteenth annual meeting at Richfield Springs, N. Y., on the 2d, 3d, and 4th of September, under the presidency of Dr. Prince A. Morrow, of New York. The programme includes an address by the president; Observations on Prurigo, Clinical and Pathological, by Dr. R. W. Taylor; Prurigo in the Negro, by Dr. R. B. Morrison; A Clinical Study of Pruritus Hiemalis, by Dr. W. T. Corlett; A Study on Pruritus, by Dr. E. B. Bronson; Note relative to a Case probably of Cancer *en cuirasse*, by Dr. J. N. Hyde; A Case of Atrophia Maculosa et Striata following Typhoid Fever, by Dr. F. J. Shepherd; Electrolysis in the Treatment of Lupus Vulgaris, by Dr. G. T. Jackson: Immigrant Dermatoses, by Dr. J. C. White; Notes on some Rare Cases, by Dr. G. H. Fox; Cases of Cutaneous Tuberculosis, with Histological Studies, by Dr. J. T. Bowen; Cases from the Hopkins Hospital Clinics, by Dr. R. B. Morrison; Plica, by Dr. H. W. Stelwagon; The Treatment of Erysipelas, by Dr. C. W. Allen; Remarks on the Treatment of Dermatitis Herpetiformis, by Dr. L. A. Duhring; The Treatment of Ringworm and Favus of the Scalp, by Dr. H. W. Stelwagon; Notes on Pilocarpine in Dermatology, by Dr. H. G. Klotz; and A Report on Aristol, by Dr. C. W. Allen.

An Honorary Degree.—The *Journal of the American Medical Association* announces that Fort Wayne College has conferred the honorary degree of LL. D. on Dr. W. W. Dawson, of Cincinnati.

The late Dr. William Brodie, one of the best-known physicians of Detroit, died on the 30th of July, at the age of sixty-seven. The deceased was a native of England, and a graduate of the College of Physicians and Surgeons, New York, of the class of 1850.

The Death of Professor Arnold.—The *Prager medicinische Wochenschrift* announces that Dr. Friedrich Arnold, emeritus professor of anatomy in the University of Heidelberg, died recently in the eighty-eighth year of his age.

The Death of an Aged Physician.—Dr. Isidore Labatut, who died recently in New Orleans, is said to have been the oldest physician in the United States. He was born in April, 1793.

The Antiseptic Treatment of Typhoid Fever.—"According to Dr. Petresco, who has been employing bisulphide of carbon in the treatment of typhoid fever, the difference in the mortality of cases treated in this way from that of cases treated according to more usually recognized systems is very considerable. The mixture prescribed was of the strength of two per cent., the vehicle being mint water. Of this mixture from three to four ounces were ordered daily. The mortality of typhoid in Bucharest is generally from twenty-five to thirty-eight per cent., but under the bisulphide-of-carbon treatment Dr. Petresco lost only ten per cent. of his cases. Even more remarkable were his results with β-naphthol, of which from forty-five to sixty grains were given *per diem*. Under this treatment he lost only four per cent. of the cases. Sometimes wet sheet packing was combined with the internal medication, sometimes not. He states that not only was the mortality diminished under bisulphide of carbon or β-naphthol, but that the whole course of the disease was rendered milder, and there was a remarkable immunity from serious complications."—*Lancet.*

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from July 27 to August 2, 1890:*

PRICE, CURTIS E., Captain and Assistant Surgeon, is, with the approval of the Acting Secretary of War, granted leave of absence for ten days. Par. 3, S. O. 175, A. G. O., Washington, D. C., July 29, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 2, 1890:*

BLACKWOOD, N. J., Assistant Surgeon. Ordered to duty in the Bureau of Medicine and Surgery.

WALES, P. S., Medical Director. Ordered to duty in charge of the Museum of Hygiene.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the three weeks ending July 26, 1890:*

BAILHACHE, P. H., Surgeon. Granted leave of absence for seven days. July 26, 1890.

HUTTON, W. H. H., Surgeon. To proceed to Chicago, Ill., on special duty. July 24, 1890.

GODFREY, JOHN, Surgeon. Granted leave of absence for thirty days. July 21, 1890.

PECKHAM, C. T., Passed Assistant Surgeon. When relieved at Memphis, Tenn., to proceed to St. Louis, Mo., and assume command of the Service. July 9, 1890.

DEVAN, S. C., Passed Assistant Surgeon. Granted leave of absence for twenty-five days. July 15, 1890.

KALLOCH, P. C., Passed Assistant Surgeon. Orders of July 5th, to St. Louis, Mo., revoked. July 8, 1890.

WILLIAMS, L. L., Passed Assistant Surgeon. Relieved from duty at Baltimore, Md., and to assume command of the Service at Memphis, Tenn. July 8, 1890.

PERRY, T. B., Assistant Surgeon. To proceed to Baltimore, Md., for temporary duty. July 17, 1890.

STONER, J. B., Assistant Surgeon. Granted leave of absence for thirty days. July 21, 1890.

HUSSEY, S. H., Assistant Surgeon. To proceed to Pittsburgh, Pa., for temporary duty. July 18, 1890.

YOUNG, G. B., Assistant Surgeon. Granted leave of absence for fifteen days on account of sickness. July 12, 1890.

STIMPSON, W. G., Assistant Surgeon. To proceed to Buffalo, N. Y., for temporary duty. July 12, 1890.

HOUGHTON, E. R., Assistant Surgeon. To report to the medical officer in command, New York Marine Hospital, for temporary duty. July 14, 1890.

Promotion.

MAGRUDER, G. M., Passed Assistant Surgeon, to rank as such from July 12, 1890.

Appointments.

HOUGHTON, E. R., Assistant Surgeon, to rank as such from July 12, 1890.

BENEDICT, A. L., Assistant Surgeon, to rank as such from July 24, 1890.

Letters to the Editor.

THE PIN-WIRING TREATMENT OF FRACTURE OF THE PATELLA.

HILLARY PLACE, LEEDS, ENGLAND, *July 19, 1890.*

To the Editor of the New York Medical Journal:

SIR: In your issue of June 21st I notice a letter by Dr. Frank S. Low, in which he advocates the treatment of simple fracture of the patella by wiring by means of pins placed above the upper fragment and below the lower, both being outside the joint.

I have already not only advocated but practiced this method of treatment on several occasions, and had the honor of showing one of my cases before the London Clinical Society in 1889.

A full account of the method of procedure will be found in the Clinical Society's Transactions.

A. W. MAYO ROBSON.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN OBSTETRICS AND GYNÆCOLOGY.

Meeting of May 22, 1890.

Dr. R. A. MURRAY in the Chair.

Artificial Prolapse of the Uterus; its Risks.—Dr. H. C. COE read a paper with this title. He thought that artificial prolapse of the uterus was only brought about either for the purpose of making a thorough examination or of facilitating operative procedures on this organ. Judging from the amount of literature on this subject in the foreign journals and publications, it would seem that this practice was indulged in to a much greater extent there than in this country, where it had now become almost obsolete. That it had been productive of considerable harm there could be no question. Dragging these parts out of all anatomical relations, even if there was no disease present, had of itself been the cause of much trouble. Where there was disease around the uterus the procedure was decidedly unsafe. While this method had been used as a routine in the aid to diagnosis and to render more easy operations upon the cervix, the speaker thought that it showed a lack of skill on the part of the diagnostician and operator to have to resort to such practice, and that cures were really very rare where such a method was necessary. The dangers to be apprehended from the procedure were numerous. The tissues were apt to be overstretched even if in a normal condition. Again, there was danger of straining the already relaxed tissues. Rupture of the tubes and ovaries was an accident to be looked for, and also the setting up of peri-oophoritis by dragging on the broad ligaments. Any of these complications were liable to come on after artificial prolapse. The writer did not operate upon an immovable uterus with it in the normal position, and would under no consideration drag it down at such a time. The writer had seen several cases where, with the patients under anæsthesia, the uterus was found to be freely movable, and yet accidents had resulted after this practice. The skilled operator ought not to find it necessary to pull down the uterus, but merely to steady it in the normal position for any of his manipulations.

Dr. H. T. HANKS agreed with the writer of the paper as to the question of danger of such procedures, but said that when it was necessary he resorted to the method. He had been much impressed with the dangers that patients were exposed to in the routine of clinic examinations, as they were frequently found to be much worse on the days following such visits.

Dr. H. J. BOLDT had formerly resorted to artificial prolapse in every case that came to his clinic. He was quite sure that he had had frequent trouble following such examinations, and,

as he had gained nothing in diagnosis by this means, he had now discarded the practice. It was his custom, when making a thorough examination, to place the patient under an anæsthetic and to examine the parts with them as nearly in the normal position as possible, using the utmost antiseptic precautions.

Dr. A. P. Dudley had laid down two cardinal rules from which he never deviated. Those were, first, that he always used every care in his antisepsis, and, secondly, that he never made traction on the uterus when there was any existing tenderness. He thought that in the examination of fleshy women the bimanual method did not give good results, but that in these cases a finger in the rectum and another in the vagina was more satisfactory. He was also quite sure that many cases of acute trouble had followed artificial prolapse.

Dr. McLean heartily indorsed the sentiments expressed by the writer of the paper and the gentlemen who had preceded him. He did not think that as a routine this method was much followed in this country simply as an aid to diagnosis, but that it was confined to the operation of trachelorrhaphy.

Dr. G. M. Edebohls said that he had had no experience with this method, but did not think it impossible that the evil results might be due to some other cause than traction on the uterus alone, as the introduction of a sound was done at every examination. He thought that all operators had been guilty of more or less traction on the uterus at some time or other, and that he had seen deaths following such trivial causes. He was not sure whether they had not been due to sepsis rather than to traumatism.

The Chairman had seen a number of bad results following artificial prolapse, but thought that some of the troubles might be due to the introduction of the sound. It was not uncommon after trachelorrhaphy to find the anatomical results perfect but the pelvic trouble much worse.

The Immediate Repair of Injuries to the Pelvic Floor.—This was the subject of a paper by Dr. I. H. Hance. He thought that in the present aseptic practice of midwifery the operation had the best chances of success, and that only under the most exceptional circumstances should it be put off. He confined his immediate operation to those cases in which the laceration had not extended through into the rectum. These were either where there was a clean cut through the perinæum, or through the skin and perinæum to one side or other of the median line. There was another class in which this immediate repair offered good results, and that was where the posterior vaginal wall had been ruptured without laceration of the skin. The speaker thought that there ought to be no difficulty in recognizing these incomplete lacerations at or just before delivery, thus gaining time to make the necessary preparations to repair them at once. For the operation the patient was placed in the lithotomy position. The parts were then washed with an antiseptic solution. The first suture was introduced high up in the vagina above the tear. If the laceration had extended up on both sides, they were to be repaired separately, great care being taken to get the lips of the wound in perfect apposition. After as many sutures had been introduced as were necessary to accomplish this, another douche was given, the parts were dusted with iodoform, a pad was applied, and the legs were tied together, to remain so for twenty-four hours. The bowels were moved on the third day. The speaker's reason for beginning the suturing high up on the vaginal wall was that by this means the formation of pockets was avoided, and also that he thought this method offered the best results for the restoration of the pelvic floor. Statistics on the subject showed that the largest percentage of successful operations on the pelvic floor were those of immediate repair, the percentages of cures ranging all the way from thirty-eight per cent. to ninety per cent. Another deduction from careful research was that, of all primiparæ, fully twenty-five per cent. suffered more or less laceration. The author then related the histories of several cases of various degrees of lacerations, and the special method adopted in each particular case, the operation in all yielding perfect results. In closing his paper he said that the two points to be closely observed that success might attend the immediate operation were, first, the careful adaptation of the lips of the wound, numbering the sutures to individual requirements; and, secondly, the observance of strict antiseptic precautions.

Dr. C. T. Jewett thought it possible that, if labor was retarded, the percentage of lacerations could be reduced. In his method of suturing he had combined the vaginal and skin suture, but, of course, the vaginal was better if the laceration was high up. He did not pass the suture around the wound, as he thought by this means there was too much tension and puckering of the tissues, but through the lips of the wound, using as many catgut sutures as it required to make apposition perfect. He used catgut sutures, because he had always found them satisfactory. In a case where there seemed to be danger of laceration it was his practice to perform double episiotomy, and then, immediately after delivery, to repair the injury.

Dr. Dudley thought that it was always best to repair such injuries at once. He delivered his patients in Sims's position, which gave him an opportunity of watching the perinæum and preventing laceration. If this occurred, notwithstanding precautions, this position, at least, afforded easy access to the injury. With one finger in the rectum, the wound was closed with an over-and-over stitch. The speaker did not pass the suture around the wound; by this means he thought there was danger of exerting too much pressure on the tissues. He had as yet his first failure in the immediate operation to report.

Dr. Edebohls thought that it was the duty of the accoucheur, in justice both to himself and to the patients, to have the laity understand that such accidents could not always be helped. He had performed a number of immediate operations, and had had no failures. He agreed with the writer of the paper when he said that the vagina would begin lacerating before the perinæum. This possibility could be ascertained by digital examination before delivery, and preparation be made for immediate repair as soon as delivery was accomplished. He used silk-worm gut in this operation and introduced his first suture at the apex of the tear, and continued them down to the posterior commissure. He had never been called upon to introduce more than seven sutures to bring the parts together. It was not his practice to introduce a finger into the rectum, because he wanted his fingers to remain aseptic. He had lately adopted the method of allowing the ends of the high sutures to remain long, so as to admit of easy removal. In several cases he had left the uppermost sutures *in situ* for several weeks, until the perinæum had become strong, before removing them, and had found no evil results from this practice. He had recently made an immediate operation on a patient with complete laceration, which had resulted in perfect restoration of the integrity of the parts.

Dr. Mavette's methods were essentially the same as those practiced by Dr. Hance. He also made it a point to use plenty of sutures. It was his experience to find tears in the median line more or less infrequent. He briefly reported the histories of fifty cases, with varying degrees of laceration, in which the immediate repair was made, primary union taking place in fifty-eight per cent. of the cases. He did not do his operation until oozing had ceased, for fear of a blood-clot forming and preventing primary union. At the end of twenty-four hours after operation a douche of 1 to 8,000 bichloride was used in every case.

Dr. McLean always repaired the damage as soon as possible. He thought the best apposition could be got early, as in a few

hours the parts would surely shrink away from each other. He thought that, where the parts fitted nicely together, two or three sutures were quite enough to maintain apposition until healing had taken place. He thought it an injustice to patients not to do the immediate operation.

Dr. HANKS thought that the question was not *sub judice*, but that all had agreed it should be done at once. Of the necessity of leaving no point of sepsis there could be no doubt, and that the good results of the operation depended upon the condition of the tissues and asepsis.

Dr. COE reported a case of complete laceration in which the immediate operation was done, using the continuous catgut suture, success being perfect. He was in favor of always doing the repair at once, and he used as many sutures in the primary as in the secondary operation.

The CHAIRMAN thought that it was still a question as to how this injury should be repaired, but that it should be done at once there was no doubt. He thought that the vaginal suture was the best, for, if the skin only were taken up, the deeper parts were apt to fall away and form pockets. He did not like the use of an odoriferous antiseptic, because it disguised or covered up one of the important diagnostic features of change going on in the wound upon which much dependence was placed.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION IN ANATOMY AND PHYSIOLOGY.

Meeting of March 14, 1890.

The President, Dr. PURSER, in the Chair.

PROFESSOR BIRMINGHAM exhibited (1) a right lung, the upper and inner parts of which, including the whole of the apex, were marked off by a deep fissure as a supernumerary lobe; the fissure was occupied by a fold of pleura, in the free margin of which the arch of the azygos vein was contained. By this fold of pleura the upper part of the pleural sac was partitioned off, as a pocket-like cavity, in which the supernumerary lobe lay. The anomaly was explained by supposing that the azygos vein had been displaced laterally, and that the heart in descending had pulled the vein through the substance of the lung external to the apex; (2) the two halves of the nasal fossæ—one with the mucous membrane removed, the other with the membrane intact—in which there was almost complete absence of the ethmo- and maxillo-turbinal bones.

Professor CUNNINGHAM remarked upon the rarity of the condition.

Professor BENNETT considered that it was not pathological.

The Lantern as an Aid to Anatomical Demonstrations.—Professor BIRMINGHAM gave a demonstration of the magic lantern applied to the illustration of anatomical lectures. He pointed out that the lantern might be used in daylight in a theatre with a head-light, if the screen was provided with a projecting canopy, so that the penumbra might be produced on its surface. He explained the making of slides, either by photography or by the hand; the latter method gave the most striking results for anatomical purposes. They were drawn with a fine pen in Indian ink, either upon prepared glass, prepared sheets of mica, or upon thin sheets of gelatin, which were afterward placed between two sheets of glass. He had been using this means of illustration (in addition to blackboard diagrams in colored chalks) daily for two years, and he had found it thoroughly satisfactory. He confidently advocated the systematic use of the lantern for anatomical illustration. He then showed a large number of diagrams illustrating anatomical subjects.

The PRESIDENT said that he had made experiments with the lantern in his own theatre, but his results were not so good as Professor Birmingham's when the theatre was not completely darkened. However, he did not think that the lantern ought to be allowed to replace diagrams in colored chalks.

Collective Investigation.—On the motion of Professor CUNNINGHAM, the interim reports of the Collective Investigation conducted in the Anatomical Department of Trinity College were read by the gentlemen who had charge of the different investigations, as follows:

I. Dr. W. HENRY THOMPSON—*Formation of the Portal Vein.*—Out of fifty-three cases the *inferior mesenteric* ended in the splenic in thirty, in the superior mesenteric in twenty, and in the angle between both in three. Out of forty-four cases the *coronary* ended in the portal in twenty-six cases, in the splenic in eighteen. Four chief "types" of portal were found in the forty-four subjects—(1) found in sixteen the inferior mesenteric joined splenic, coronary entered portal; (2) found in eleven the inferior mesenteric joined the superior, coronary entered splenic; (3) found in seven both inferior mesenteric and coronary entered splenic; and (4) found in seven neither inferior mesenteric nor coronary joined splenic; former joined superior mesenteric; latter joined portal. The first of these was considered normal. Out of forty-six cases the portal vein was formed at the level of second lumbar vertebra in thirty-two.

II. MESSRS. A. C. O'SULLIVAN and O. L. ROBINSON—*The Arrangement of the Renal Arteries.*—Forty-three subjects examined. In number they varied from one to four. One or more arteries always entered the hilum; in eighteen cases an accessory artery entered at the upper or lower border; accessory arteries arose from aorta or renals, except in one case, from the common iliac. In forty-six cases all branches passed between vein and ureter, in six they inclosed vein and ureter, in eleven inclosed vein only, in six ureter, and in other six all the arteries passed in front of vein.

III. Mr. J. J. LONG—*The Relation of the Internal Maxillary Artery to the External Pterygoid Muscle.*—Eighty-eight arteries examined. The artery ran superficial to the muscle in fifty per cent. of the cases, and then entered between its two heads. In forty-two cases the artery lay deeper than the external pterygoid; in nineteen of these cases the inferior dental and in seven cases the lingual nerve passed down superficial to the artery.

IV. Mr. C. E. STOKES—*The Tuberculum Laterale of the Astragalus.*—Seventy-two cases examined. Two examples of os trigonum found, in each case connected to the astragalus by a synovial joint, which communicated with the posterior astragalo-calcaneal, and in each case the os trigonum gave partial attachment to the posterior fasciculus of the external lateral ligament of the ankle joint.

Professor CUNNINGHAM reminded the Section that this was the second report of the collective investigation read before the Academy. Last year different and, in his opinion, more interesting subjects had been taken up and reported upon. A somewhat similar collective investigation was instituted late last year in connection with the Anatomical Society of Great Britain and Ireland, which it was proposed to extend to all the schools in these countries; this placed the anatomical department with which he was connected in a dilemma. While extremely anxious to take part in the general work, yet they felt that this result ought to belong to the Academy of Medicine in Ireland. After some correspondence on the matter it had been arranged that the programme of the Anatomical Society should be adopted, but that the reports from the Irish branches should be read at the Academy of Medicine in Ireland, published in its Transactions, and then handed over to the Anatomical Society.

Professor Birmingham said that the gentlemen who had carried out the investigation deserved the thanks of the Section for the interesting reports which they had just read. He pointed out that Dr. Thompson's report on the termination of the inferior mesenteric vein differed from the results of Treves, who found that the vein terminated in the splenic in only eighteen per cent. of his hundred cases. Treves considered this ending a sign of higher development. Would Dr. Thompson's results therefore point to the conclusion that the Irish whom he examined were more highly developed than those examined by Treves?

Professor Bennett was glad that the reports of the collective investigation had been brought before their Academy, instead of being handed over to the Anatomical Society. Some years ago there had been a collective investigation instituted in London for the purpose of examining into the pathology of hydrophobia. He had fortunately obtained a spinal cord at a post-mortem in a case of hydrophobia; he had sent the cord intact as directed to London, but from that day to this he had never heard one word about that cord. So he thought they had better do their own work at home.

The Parieto-occipital and Calcarine Fissures of the Brain; their Development and Relation to the Calcar Avis.—Professor Cunningham made a communication, illustrated with diagrams, on the development of the parieto-occipital and calcarine fissures and their relation to the calcar avis. He referred to the conflicting views held regarding the development of these fissures, the difficulty in connection with their study being due to the fact that their origin was synchronous with that of the transitory fissures of the brain, and they lay in series with them. For those early fissures corresponding in position to the parieto-occipital and calcarine he proposed the name of "precursors" of these fissures. He traced the connection between the precursors and the permanent fissures, and showed how the history of either of the two fissures might be made out, not only in the brain of the seven months' fœtus, but even, in most cases, in the adult brain. He also adduced phylogenetic evidence in reviewing the question, but he showed that this was in several respects at variance with the ontogenetic evolution of the fissures under consideration.

Professor Birmingham said that the fissures discussed by Professor Cunningham were very unsatisfactorily dealt with in the usual descriptions of their development. He asked what eminence each fissure produced in the interior, if each produced a separate eminence in the adult brain.

Professor Cunningham replied that there was one eminence in the interior—the calcar avis—which belonged sometimes to the calcarine, sometimes to the parieto-occipital fissure, according as the stem of the "Y"-shaped fissure formed in the adult by the union of these two fissures belonged to the former or the latter fissure.

SECTION IN PATHOLOGY.

Meeting of March 21, 1890.

The President, Dr. Bennett, in the Chair.

Lympho-sarcoma of the Neck.—Dr. J. K. Barton presented the following case of lympho-sarcoma of the neck: A tumor, occupying the whole of the right side of the neck, had been growing for four years, the first three of which it was only of the size of a filbert-nut. It had then suddenly commenced to grow, and attained its present size in three months. Fluctuation was elicited in one part. Edges undefined. Diagnosis, a lympho-sarcoma, which had burst through the capsule and had become diffused through all the structures of the neck. The patient, a strong, robust countryman, had become subject to fits of a remarkable kind. He had suddenly become pale, fell over if sitting up, his pulse disappeared, and he had lost consciousness for about a minute. He had then recovered; his color and pulse had returned, and he had sat up. An operation was performed, to see how far the growth could be removed, in the course of which the common carotid artery of the right side of the neck, lying behind the tumor and compressed by it, was found to be completely occluded. At its bifurcation a rent was torn in it, but no blood escaped; it was firmly occluded lower down. The speaker drew attention to three pathological facts of interest: 1, the growth of the tumor; 2, the fits from which the patient suffered, which may have been produced by the compression of the pneumogastric nerve by the tumor; 3, the occlusion of the carotid artery by the pressure of the growth upon it and around it.

Tumor of the Brain; Atrophy of the Right Kidney, with Compensatory Hypertrophy of the Left Kidney.—Dr. Joseph Redmond showed the brain and kidney which were removed from the body of a patient, aged twenty-nine, who died in the Mater Misericordiæ Hospital on April 30, 1889. The patient had received a severe blow of a baton over the right ear in December, 1888, which had stunned him somewhat. From that time until his death he had complained of severe pain in the right side of his head, and had also suffered from fits, which had occurred at intervals of about a week. During these attacks he was apparently unconscious, but the patient stated that he was thoroughly conscious of all that was passing around him at the time. These attacks were characterized by some of the ordinary symptoms which were present in epileptic seizures; the patient simply sank into an apparently unconscious condition, which lasted for ten or fifteen minutes. On the evening of his death the patient had had a number of such attacks, during one of which he had expired. The autopsy showed a slight depression at the posterior portion of the right parietal bone, to which the dura mater adhered. On examining the brain, a tumor somewhat larger than a pigeon's egg was found in the region of the angular and supramarginal gyri, which extended into the substance of the hemisphere. The right kidney was found to be atrophied and the left hypertrophied.

Dr. McWeeney said the peripheral portion of it consisted of small-celled structure, but the internal portion of the tumor was structureless. It was surrounded by thick connective tissue, in which could be seen numerous small thickened blood-vessels. The specimen under the microscope showed the disappearance of the nerve-fibers from the cortex of the brain in the immediate neighborhood of the tumor. The latter was of a syphilitic character, as far as he could make out. He did not see any reason to regard it as tubercular. There was a small scar in the liver, which looked like a result of tertiary syphilis. Why he regarded the tumor as syphilitic was that it involved both the pia mater and the dura mater, which were adherent together.

Lupus of the Larynx.—Dr. Walter Smith exhibited the larynx of a man who had died of pneumothorax consequent upon extensive tubercular disease of the lungs. There was also amyloid degeneration of the liver, spleen, kidneys, and intestines. Fourteen years previously Dr. Bennett had successfully performed the Indian operation for an artificial nose, owing to the destruction effected by old-standing lupus of the face. At the post-mortem examination both lungs were found riddled with vomicæ. Tubercle bacilli were found in their contents. The larynx was involved to a considerable extent. The free edge of the epiglottis had nearly disappeared; what remained was thickened and irregular. There was no ulceration of the

cords, true or false. Between the arytænoids were several pyramidal outgrowths, projecting above and below the rima glottidis. The case illustrated the supervention of tubercular phthisis upon cutaneous lupus, and was compared with Leloir's case of lupus of the face, tongue, and larynx, published in the *International Atlas of Rare Skin Diseases.*

Rupture of the Heart.—The PRESIDENT exhibited a case of rupture of the heart. The man had been found dead on the railway with several fractures of the limbs and a scalp wound, but no fracture of the skull. They found no external sign or trace of injury to the thorax in front. A large portion of the sternum was detached from the rest of the skeleton and thrust down on the underlying viscera, all the costal cartilages being broken as well from the second to the eighth. The pericardium and the pleura were found full of blood. At the apex of the right ventricle there was a large rupture. There was another great rent into the right auricle. There was no laceration, neither was there any blood-clot in the heart, nor any rupture of the valves or of the chordæ tendineæ. In the auricular appendix and the musculi pectinati there were two small ruptures. In the back of the heart, at the left auricle, in the interval between the entrance of the pulmonary veins, there were two or three large lacerations. The left auricular appendix was ruptured; but the left ventricle was free of rupture, or of any lesion whatever. Clearly what happened was, that, the heart being full of blood, pressure of the detached bone burst the whole of the three chambers.

LETTERS TO MY HOUSE PHYSICIANS.

BY WILLIAM OSLER, M. D.,
BALTIMORE.

LETTER II.

BERN, *May 21, 1890.*

DEAR T.: Within an hour after reaching Basel we were in the *Vesalianum*, as the anatomical institute is called, looking for the skeleton which Vesalius presented to the university when he was here in 1542–'43 supervising the printing of his great work. Historically this is probably the most interesting museum specimen in existence, and to Professor Roth is due the credit of determining accurately the fact of its association with Vesalius. Several years ago he sent me his paper on the subject, an abstract of which you will find in the *Medical News* for 1887 (or 1888), in an editorial note. The plates of his work were drawn from this skeleton, which is treasured by the Basel faculty as a most precious relic. Above the glass case in which it is contained is the inscription: "*Männliches Skelet das der Meister der Anatomie Andreas Vesal, aus Brüssel, der hiesigen Universität schenkte als er 1543 sich in Basel aufhielt um der Druck seines grossen anatomischen Werkes zu besorgen.*" Well may he be called the Master of Anatomy, the great Reformer in Medicine, for his work loosened the chains of tradition in which the profession had been fast bound for centuries. His was a bold and venturesome spirit which could dare dispute the statements of Galen and Hippocrates, dogmas revered by the physicians of the sixteenth century as are to-day those of Calvin and of Luther by certain theologians. Professor Roth has recently published an interesting paper (*Quellen einer Vesalbiographie*, Basel, 1889), in which he has given the results of his researches among the archives of the University of Padua, and he has determined definitely for the first time the date and place of the graduation of Vesalius—Padua, December 5, 1537. Please note, too, that he was a young man when he published his great work, another illustration of the theory upon which I am always harping, that a man's productive years are in the third and fourth decades.

It is not a little remarkable that the skeleton should be in such a state of preservation; but above it lies another, prepared by Felix Plater, a renowned Basel professor of the sixteenth century, also in excellent condition.

The Basel Hospital is an old building but very conveniently arranged and with beautiful gardens, in the middle of which is a large summer ward for women and children. I am much indebted to Director Hoch for his kindness in showing me the different departments. In the operating room the table is constructed of zinc with a hot-water chamber, above which is a perforated plate so that irrigation can be carried out. The warming-pan—of which it is practically only a special example—is also perforated in the middle for the escape of the solutions. I am sure that for prolonged operations this is a great advantage in counteracting the depression so liable to occur both from the shock and from the anæsthetic. Not ten days ago I saw the same arrangement in use at the Physiological Laboratory of University College, London, in a prolonged experiment upon the brain of a monkey. Professor Schäfer told me that they had found the animals stood the operations very much better and revived more promptly if the body temperature was kept up in the artificial way. So important did he seem to think it that additional hot water was put in at the end of about an hour and a half.

We found Professor Socin in the operating-room with a class of about thirty men, a patient on the table, and a senior student in the arena, who, during the course of an hour, underwent a most searching examination on tuberculosis of joints and on the particular case before them. It was certainly a most instructive method of procedure, and it was fortunate the poor patient was deaf, as the questions of prognosis and of treatment were discussed thoroughly. Amputation of the leg was then performed, as the disease had progressed too far for resection. We could not but feel, however, that it was hard to keep the poor man waiting on the table. Certainly the ward would have been the more appropriate place for the instruction. The Basel students have an exceptionally clear and decisive teacher of surgery; here again the colored chalks on the blackboard were used at least half a dozen times to illustrate special features of the disease and steps of the operation.

Professor Immermann has charge of the medical clinic, and has a conveniently arranged, though not large, clinical laboratory. The lecture-room is attached to the medical wards, and we heard for half an hour a very practical talk on the treatment of acute Bright's disease. A point specially insisted upon in the later stages was the flushing of the tubes by a plentiful supply of liquids. Then the class was taken into one of the men's medical wards, and a student examined a case of typhlitis, upon which the comments of Professor Immermann were very interesting. The young man had been seized five days before with pain in the right iliac region, not of an agonizing character, and moderate fever, so that he had to give up work. He had not been particularly constipated prior to the onset of the pain, but he had had, several years ago, a somewhat similar attack. The examination showed simply pain on deep pressure in the right iliac fossa, no tumor, no signs of peritonitis. The case was regarded as one of appendicitis, and, as the symptoms had progressively improved, the treatment was confined to the administration of opium and the use of local applications. Great stress was laid on the absence of tumor as a differential point in the diagnosis of appendicitis and typhlitis from fæcal impaction. I gathered that Professor Immerman believed in the existence of a typhlitis apart from appendix disease; and the tumor, which is more apt to be present in these cases, may be due either to primary impaction or to fæcal stasis in the cæcum in consequence of the inflammation. Now, this was a case which illustrated the point I mentioned in my letter to L. I have not the slightest doubt that, if a laparotomy had been performed, an inflamed and adherent, possibly a perforated, appendix would have been found, yet the lad was recovering under ordinary measures. Still, the risks are very great, balancing those of an operation even at this early stage, as perforation into the general peritonæum is always imminent, and then there is the liability to recurrence, as shown, indeed, in this case.

In the Vesalianum one of the Privat Docenten, von Lenhossék, showed us the method of preserving subjects, which is that of Laskowski, of Geneva. An injection of glycerin with carbolic acid, with a little alcohol, is first made, and then the ordinary Teichmann's mass, consisting of putty and bisulphide of carbon, with a suitable coloring

ingredient. A preliminary washing out of the blood-vessels is advisable. In Geneva the subjects are wrapped in sheets, which are sprinkled with water, and Ramsay Wright tells me that the bodies were in an excellent state of preservation. Von Lenhossék said that they found it necessary to use alcohol in the tanks. The muscles are certainly very well kept by this method, and the dissection is said to be easier than in bodies preserved with the bichloride of mercury.

In the pathological laboratory Professor Roth showed us a recent specimen of enormous epithelioma which had developed in an old leg ulcer, the result of a fracture many years before. The tumor had involved the bone and the leg had to be amputated. Under his direction, Dr. Dubler, the assistant, has been making an interesting research on suppuration, which has just been published. He comes to the conclusion, from a very large series of experiments, that the pus formation which follows the injection of chemical substances is the result of a delimiting inflammation about a primary necrotic area, and in the same way bacteria act by causing a necrosis, which the suppuration removes, so that there is no essential difference between the process in the two cases.

Here in Bern we found a model hospital on the pavilion plan, situated on a sloping hill on the outskirts of the town, and from the wards there is a magnificent view of the Bernese Oberland. The appearance of the pavilions, rising one above the other in the grounds, is very effective, and the new Royal Victoria Hospital in Montreal, which is also to be on the side of a hill, will, I think, resemble this very much. The Pathological Institute is a large, separate building, with every possible convenience for teaching and research. Professor Langhans was kind enough to show us all his treasures, not the least interesting of which was the skeleton of a bicapitate monster, presented to the university over a hundred years ago by the great Haller, who was a Swiss, and who lived near Bern, I believe, after his retirement from Göttingen. In the post-mortem theatre I was glad to see that to the students' desks towels were attached, a convenience rarely met with.

The medical clinic is in charge of Professor Sahli, a comparatively young man, appointed last year. There are two stories in the chief medical pavilion, with four wards, and there is accommodation for about-eighty patients. Connected with it by a covered passage is the lecture-room, with seats for about one hundred students. A very complete electrical equipment and tables for urinary and microscopical examination are on either side of the arena. There were eighty-four students at the clinic, eighteen of whom were women. After a careful analysis with a student of the chief points in the history and treatment of whooping-cough, a case of diabetes was brought in from the wards, and the next *Praktikant* on the list happened to be a woman, who went through the ordeal of questions in the various modes of testing for sugar in the urine. The saccharometer of Hermann and Pfister was shown, and then, after the clinic, those students who so desired had an opportunity of seeing the practical working of the apparatus. On either side of the amphitheatre is the clinical laboratory, with bacteriological, chemical, and microscopical rooms, large, admirably equipped, and very convenient to the wards. Bern is one of the Swiss schools most frequented by women, of whom about fifty are at present in attendance. I was told by one of the professors that they were good students; as a rule, very attentive and industrious, but not always sufficiently prepared in the preliminary subjects. Those at the lecture were all young, but I did not see one who looked likely to become the Trotula of the twentieth century.

Book Notices.

Insomnia and its Therapeutics. By A. W. Macfarlane, M. D., Fellow of the Royal College of Physicians, Edinburgh; Fellow of the Royal Medical and Chirurgical Society of London, etc. London: H. K. Lewis, 1890. Pp. xv–366.

The physiology of sleep, the value of insomnia as a symptom in varied psychic and physical conditions—neuroses, organic nerve troubles, toxic states—and the treatment best adapted to each and all, together with hints and cautions concerning certain peculiarities in the manifestations of wakefulness, form a most interesting volume that is alike valuable and delightful reading. The work is plain, practical, clinical, and is the last word upon a subject of peculiar moment to Americans, who are literally the most wide-awake nation in the world, insomnia being the price paid for making business our only recreation. Even a passing view of Dr. Macfarlane's book must give us pause and show how evil wakeful ways can be mended..

Practical Photo-micrography by the Latest Methods. By Andrew Pringle, F. R. M. S., President of the Photographic Convention of the United Kingdom, 1889, etc. New York: The Scovill and Adams Company, 1890. Pp. 185.

The author gives in this book practical instructions in the photography of microscopic specimens, and has written especially for those who follow the natural and medical sciences rather than for amateur investigators. Whoever is interested in an art which, like all forms of photography, has its captivating qualities, will find in Mr. Pringle's well-illustrated volume a thorough and trustworthy guide.

A Treatise on Headache and Neuralgia, including Spinal Irritation and a Disquisition on Normal and Morbid Sleep. By J. Leonard Corning, M. A., M. D., Consultant in Nervous Diseases to St. Francis's Hospital, etc. With an Appendix. Eye-strain, a Cause of Headache. By David Webster, M. D., Professor of Ophthalmology in the New York Polyclinic. Illustrated. Second Edition. New York: E. B. Treat, 1890. Pp. 10–15 to 259. [Price, $2.75.]

The principal change in this edition is the addition of a short article by Dr. Webster, in which he gives the details of a number of cases in which correction of refractive errors, impaired accommodation or insufficiency of the extrinsic ocular muscles, has relieved persistent headache. Otherwise the work seems to merit the same praise and to be open to the same criticism as the first edition. In many respects it is very valuable. The author's inventive ability may stand him and the profession in good stead. The work is very readable and well got up.

BOOKS AND PAMPHLETS RECEIVED.

Diseases of the Rectum and Anus, their Pathology, Diagnosis, and Treatment. By Charles B. Kelsey, A. B., M. D., Professor of Diseases of the Rectum at the New York Post-graduate Medical School and Hospital, etc. Third Edition, rewritten and enlarged. With Two Chromo-lithographs and One Hundred and Sixty-eight Illustrations. New York: William Wood & Co., 1890. Pp. x–483.

Familiar Forms of Nervous Disease. By M. Allen Starr, M. D., Ph. D., Professor of Diseases of the Mind and Nervous System, College of Physicians and Surgeons, New York. With Illustrative Diagrams and Charts. New York: William Wood & Co., 1890. Pp. xii–339.

A Pharmacopœia for Diseases of the Skin, containing a Concise Formula, Baths, Rules of Diet, Classification, and Therapeutical Index. Edited by James Startin, Senior Surgeon to the London Skin Hospital, etc. Second Edition. London: Harrison & Sons, 1890. Pp. 4–5 to 35.

Cases of Successful Operation for Bulbo-membranous Close Stricture by Internal Urethrotomy. By E. R. Palmer, M. D., Louisville, Ky.

A Case of Locomotor Ataxia associated with Nuclear Cranial Nerve Palsies and with Muscular Atrophies. By Frederick Peterson, M. D. [Reprinted from the *Journal of Nervous and Mental Diseases.*]

The Reconstruction of Deformed Noses by grafting a Portion of the Finger. By James P. Parker, M. D., of Kansas City, Mo. [Reprinted from the *Medical News.*]

A Case of Hæmatoma of the Ovary following Chronic Catarrhal Salpingitis, with Operation and Recovery. By R. Harvey Reed, M. D.

Extra-uterine Pregnancy. The History of, by Dr. W. G. Miltenberger. Laparotomy for, with Report of a Successful Case, by Dr. T. A. Ashby. Review and Discussion, by Dr. H. A. Kelly. Papers read before the Obstetrical and Gynæcological Society of Baltimore, January 4 and February 11, 1890.

An Investigation into the Ætiology of Phthisis. By Heneage Gibbs, M. D., and E. L. Shurly, M. D. II. On the Clinical History of Phthisis Pulmonalis. By E. L. Shurly, M. D., IV. On the Ætiology and Local Treatment of Phthisis Pulmonalis. By E. L. Shurly, M. D. [Reprinted from the *American Journal of the Medical Sciences.*]

A Successful Case of Nephrectomy. By George Ben Johnston, M. D., Richmond, Va. [Reprinted from the *Virginia Medical Monthly.*]

Reports on the Progress of Medicine.

DERMATOLOGY.

By GEORGE THOMAS JACKSON, M. D.

Aristol is, according to Eichhoff (*Monatshft. f. p. Dermat.*, 1890, x, 85), a dermatological therapeutical remedy of great usefulness. Last year this physician gave the weight of his authority to medicated over fatty soaps, presenting their virtues in most enthusiastic phrases. With no less enthusiasm does he now introduce to us "aristol," and were all he says of it substantiated by future experience, we should then have a specific and sure cure or varicose ulcers, seborrhœal eczema, lupus vulgaris (!!), psoriasis, trichophytosis capitis (!!), scabies, aud ulcerating syphilides (!!). His prophetic vision descries surgical joint and bone diseases, gynæcological complaints, tuberculosis, whether general or local, and constitutional syphilis flying discomfited and falling dead before this combination of iodine and thymol. The drug is described as insoluble in alcohol, in glycerin, and in water, and soluble in ether and in fatty oils. It combines all the virtues of iodoform and thymol without the disagreeable odor of the former. It may be used in the strength of ten per cent. Thus far the only thing that has not yielded to its power is the soft sore.

Aristol in the Treatment of Naso-pharyngeal Syphilis.—This new drug has found another admirer in the person of Dr. Schuster, of Aachen, who reports (*Monatshft. f. prakt. Dermat.*, 1890, x, 262) very favorably upon its use in naso-pharyngeal syphilis. The case reported was one of ulceration of the pharynx and nose, and the treatment consisted in applying to the parts finely pulverized aristol by means of a powder-blower. Inunctions and iodide of potassium were also employed in the way of general treatment. Within ten days there was a great improvement of all the conditions, and within three weeks the throat was well and the nose nearly so. [Which was the most active agent here in promoting recovery? In testing new remedies, the new remedy should be used alone, otherwise the test is of little value. This is often forgotten.]

Aristol in the Treatment of Psoriasis.—Dr. Schirren, Assistant Physician, Lassar's Cliuic, reports (*Berlin. klin. Woch.*, March 17, 1890) good results in the treatment of ten cases of psoriasis by means of this new drug. It acts slower than chrysarobin or pyrogallol. The strength of the ointment used was ten per cent.

Hydroxylamine in the Treatment of Skin Diseases has been found by Dr. Groldeck, of Berlin (*Monatshft. f. prakt. Dermat.*, 1890, x, 162), to be superfluous, as we already have many other ageuts that are better. He tried it in twenty-three cases, and found it practically worthless. It is poisonous in strong solutions, and also irritating to the skin.

The Pathogenesis of Erythema.—Besnier gives us (*Annal. de derm. et de syph.*, 1890, i, 1) a study of the pathogenesis of erythema multiforme and scarlatiniforme, which he intends as an introduction to a reconstruction of our ideas in regard to the whole class of erythemas. The same form of erythema may be idiopathic, primitive, or autogenous; may arise from some toxic agent from without or an infectious element developed from within in the course of some morbid state. All individuals are not equally susceptible to erythemas, and this individual predisposition is an element of the first order in the pathogenesis of erythema. It is inborn in most subjects and shows itself in infancy by a peculiar susceptibility to all pruriginous dermatoses. In these cases it is permanent. In others it is acquired under the action of some morbid state of the body, and is then transitory and secondary. The individual predisposition being present, common causes act to call out the eruption, either by setting at work the morbid aptitude and provoking the determination, or by placing the individual in an inferior state of resistance and creating the pathological opportunity, or favoring the evolution of the pathogenous element in the organic apparatus. Such is the action of cold, one of the principal common causes of erythema multiforme. When the external circumstances are very pronounced, many individuals who are predisposed to erythema may be affected at the same time, but they never produce true epidemics. What have been called epidemics of erythema multiforme are not such in fact, but are simply erythemas secondary to zymotic diseases, such as cholera, influenza, dysentery, etc., or are abortive and wrongly diagnosticated cases of contagious fevers, such as rubeola, or certain alimentary intoxications, all of which disappear if the accidental cause is removed. Erythema multiforme is a vaso-motor disturbance producing a determination of blood to the skin, diffuse albuminous œdema, serous exudation, and finally desquamative exfoliation. These pathological processes are not exclusively confined to erythema, but are well marked in it. The agent that will excite an angeioneurosis and an erythema is neither unique nor specific. It may act from without exclusively upon the surface, or may be produced within in all sorts of ways. External irritants, absorption of septic substances, poisonous inoculations, microbian proliferations, adulterations of the blood, autogenous or other, may each and all produce an identical erythema. But the irritant itself is not specific, nor can it give rise to erythema in another healthy subject. It would seem that the exciting irritation is conveyed to the vaso-motor centers and thence reflected upon the skin. There is no proof of the presence of any irritating material in the regions where the erythema is manifested. Owing to our want of knowledge of the anatomy and physiology of the vaso-motor system, it is very difficult for us to determine with precision the relation between the erythema and its cause. Our clinical studies of diseases complicated with erythema are obscured in their results by the fact that medicines are often administered at the same time. For a long time rheumatism has been thought to have a causal relation to erythema multiforme. In reality it does not have erythema as one of its symptoms, but it may give rise to it like any other infectious disease, either directly by its proper infectious principle, or secondarily either by producing a deuteropathic infection or by rendering the individual susceptible to the action of medicines given for its cure. In cholera it is difficult to say whether the erythema is due to irritation of the nerve centers by autogenous alterations in the fluids of the body, or to the action of medicines that are generally given in large amounts. In gonorrhœa it is always a question as to the cause of the erythema. It may arise from the disease itself. Less often do the balsams give rise to it, and when the erythema occurs while a patient is taking balsams, it often of itself disappears without stopping the drugs. Typhoid fever serves but as a preparation for the erythemas that arise in its course as the result of medication or auto-toxæmia. In puerperal fever, infectious endocarditis, tuberculosis, syphilis, and leprosy, the same uncertainty of the cause of the erythema is to be noted.

Erythema scarlatiniforme is an erythema with a febrile movement during a part or the whole of its course which may be cut short or last for several weeks or months. This form is of a scarlatinal type and apt to return. Its diagnosis is often difficult, as it resembles scarlet fever so closely. But its non-specific character, its variable and prolonged course, the simultaneous appearance and prolonged coexistence of the eruption and the desquamation, its non-contagiousness, and its relapsing character, place it in the category of the erythemas. In some cases it goes beyond the bounds of erythema and takes on the nature of a dermatitis. The pathogenic conditions of erythema scarlatiniforme are as obscure and complex as those of erythema multiforme. An individual predisposition and intolerance to a number of very varied causes are essential to its production; thus we have cases due to cold and recur-

ring every year, to the use of mercury internally and externally, to the action of the sun, and to other varied causes. All of these may produce erythemas resembling each other exactly. Moreover, in these predisposed individuals the effect will last long after the cause has ceased to act, and will often be disproportioned to it.

Epithelioma Contagiosum (the new name for *molluscum contagiosum*) has been subjected once more to a careful study for the purpose of finding out what it really is. Torök and Tommasoli (*Monatshft. f. prakt. Dermat.*, 1890, x, 149) declare the disease to be contagious, and cite several unmistakable instances of contagion. Inoculation experiments proved negative in their results. Bacteriological and chemical investigations have convinced our authors that the disease is not due to a parasite. The various findings of other investigators that have been given out as parasites our authors declare to be merely artificial products of the methods used by them. Though they have failed in their inoculation experiments and have been unable to find a parasite, still they do not lose faith in the contagiousness of the disease.

Lichen Ruber and its Relation to Lichen Planus.—Toward the solution of the vexed question of the relationship of these two diseases H. von Hebra contributes an article in the *Monatshefte f. prakt. Dermat.*, 1889, x, 101. He first carefully separates lichen ruber acuminatus from pityriasis rubra pilaris, giving the diagnosis in the form of parallel columns, as follows:

Pityriasis rubra pilaris.	*Lichen ruber acuminatus.*
1. Develops in the epidermis.	1. Develops in the cutis.
2. Efflorescences bear scales from the beginning, and often consist of accumulations of epidermic scales alone which can readily be scratched off.	2. From the beginning they are smooth and glistening. Scales form only late in the disease.
3. Efflorescences limited to follicle mouths, especially those of hair follicles.	3. Are not limited to the follicle mouths.
4. Exteusor surfaces of the extremities especially affected.	4. Flexor surfaces more affected than extensor surfaces.
5. Microscopically consist of thickening of the epidermis, with lengthening of the interpapillary projections of the rete mucosum in certain places.	5. Marked collections of round cells in the papillary layers of the corium.
6. Color of efflorescences scarcely differs from that of the skin at the beginning. Afterward becomes rosy or brownish-red from consecutive hyperæmia.	6. From beginning a bright red, becoming darker, and may change to deep rusty brown.
7. Roughness of the extensor surfaces of the extremities, and satin-like smoothness on the trunk, with fine scales.	7. Everywhere thickening and roughness of the skin, increasing with the age of the disease.
8. No accompanying subjective symptoms.	8. Unbearable itching, great burning, restlessness, and jerking movements of the limbs.
9. No implication of the general health.	9. Fever, œdema (especially of lower extremities), albuminuria, sleeplessness, general prostration, and loss of weight.
10. Spontaneous recovery, or chronicity without danger to the patient.	10. Often ends in death, always attended with marasmus.
11. Cured by purely local means, though often obstinate.	11. Cured, if at all, by constitutional treatment, as with arsenic. Unna's ointment of mercury and carbolic acid good.
12. Little or no pigmentation left.	12. Deep-brown, even blackish-brown, pigmentation left which may last for months.
13. Does not affect the mucous membranes.	13. Affects mucous membranes, especially of mouth and vagina.

As to the relation between lichen ruber acuminatus and lichen planus, he believes that they are one and the same disease, because he has seen cases in which a general lichen ruber acuminatus cleared away to be followed by a lichen planus; and also cases that began as lichen planus to end as lichen ruber acuminatus. A case of each is given.

Leprosy.—The subject of leprosy is now engaging the attention of the medical profession to a marked degree. In the *Monatshft. f. prakt. Dermatol.*, 1890, No. 5, we find abstracts from three Norwegian articles on leprosy. The first is from Hansen (*Nordiskt med. Arkiv.*, Bd. xxi, No. 4), who has been studying leprosy among the Norwegians in the United States. He examined one hundred and sixty-one subjects who had either brought the disease with them or who had become affected shortly after arriving in the country. He found that the disease took the same course with them here as it does in Norway. He found not a single instance of infection of others from these, or a single case in which the disease had been passed on to the children. He believes that infection has been escaped on account of the more cleanly habits of the Norwegians living here, and the fact that the lepers have been given separate rooms and beds. Kaurin (*Norsk. Magazin f. Lægevidenskab*, 1889, iv, 5) believes that contagion is the chief cause of leprosy, and cites twenty cases of leprosy to support his thesis. Danielsen (*Report of the Lungegaardshospital* for 1886–'88) writes of the therapeutics of the disease. He has found salicylate of sodium uniformly useful in the anæsthetic form of the disease, while in the tubercular form, especially in acute outbreaks, it lessens the fever and causes the new tubercles to disappear. The old tubercles require external treatment. Ichthyol proved valueless. Unna's chrysarobin-salicylic-acid-creasote-ichthyol treatment has so far been of doubtful value. Chaulmoogra oil and salicylate of mercury influenced the disease unfavorably. Iodide of potassium favors the production of new tubercles so long as the disease is active. It is therefore useful as a test of cure. If it is administered and no new lesions appear, then the disease is probably cured.

Tuberculosis Verrucosa Cutis.—A case of this rare disease is reported by Dr. Brugger, of Würzburg (Virchow's *Archiv*, ix, 1890, 524) The disease affected the right leg of the patient. Tubercle bacilli were found in the tissues, and the disease was successfully conveyed to a guinea-pig by inoculation. The disease resembles lupus, but is to be distinguished from it by the absence of lupus tubercles, by the character of its cicatrix, which is superficial, and by not relapsing in the scar. From syphilis it differs in the slowness of its course. From elephantiasis doubtful cases can be diagnosticated only by the microscope and by inoculation experiments. It is probably identical with verruca necrogenica. We can explain the occurrence of lupus in one case, tuberculosis cutis in another, and tuberculosis verrucosa cutis in a third, diseases all depending upon one and the same cause, only upon the supposition that individual predisposition is an active determining element in the disease. It is possible that a general tuberculosis may start from the local infection which gives rise to the disease under consideration. Treatment consists in excision of the growth or in scraping it out, and the subsequent application of caustics.

Paget's Disease of the Nipple forms the subject of an exhaustive study by L. Wickham (*Annal. de derm. et de syph.*, 1890, i, 44). Beginning with a review of the history of the disease, he shows that Paget had a clear idea of the individuality of it, as he first described it as a "chronic inflammation" of the nipple. Then the idea of its being a chronic eczema developed, Butlin in 1876 so describing it. But this view held sway but for one year. Then the impression gained ground that the disease was a special dermatosis, a peculiar form of epithelioma. Various views were entertained in regard to the interpretation of the microscopical appearances of the disease, till at last Darier, in a thesis upon the disease, declared that he had discovered a parasite that caused it. Before describing the pathology of the disease, it is well to give a description of the disease itself. It is characterized by a chronic inflammation of the skin, and of the glands and their ducts, followed by the formation of an epithelioma. Though most often located upon the breast, in one case it has been seen upon the scrotum. It is rare before forty years of age; then it develops slowly and becomes epitheliomatous after from two to six years, though it may become so in a few months,

or not for twenty years. It most often affects the right breast, beginning always at the nipple. At its upper surface there are corneous concretions, little tenacious crusts, beneath which there exists at first an itching, erythematous redness, and afterward ulceration and fissures. From this time the nipple shows a tendency to retract. The areola is progressively invaded, and we have a bright-red surface, moist, desquamating or crusted in places, finely mammillated, bleeding easily, and sharply circumscribed. Upon the surface there are disseminated islands of a brilliant red and dry cicatricial appearance. Teleangeiectases may be seen here and there. The process seems to be superficial and gives to pressure a slight papyrus-like induration. Burning and itching sensations give the disease the appearance of eczema rubrum, but in doubtful cases close observation of the border of the disease will decide the doubt. It is always sharply defined, most often taking the form of a red or pale rose slight packing (*bourrelet*) raised upon the sound skin. Upon its surface are dilated capillaries, and at times there is a slight desquamation beyond it. The disease slowly extends over the areola upon the breast, taking often a rounded or oval shape. The nipple is then retracted completely, and frequently is the seat of ulceration. At times it begins as a hard lump deep down in the skin. Once established as a cancer, it develops more rapidly. Ganglionic enlargement only occurs late in the disease, as a rule.

Darier, in 1889, read a paper upon the disease before the Society of Biology in Paris, which was published in the *Bulletin médical*. He then demonstrated that the disease was due to single-celled parasites of the order of cocci or psorosperms and class of sporozoaria. These parasites have been found before, but were wrongly interpreted as cells undergoing transformation, either in the way of degeneration or of proliferation. The discovery of these psorosperms is of great importance from a diagnostic standpoint, as they, being found in the scales or in scrapings from a suspicious case, will establish the diagnosis. They were found by our author in a piece of the growth on the scrotum which Crocker showed to the London Pathological Society as a case resembling Paget's disease of the nipple. The treatment of a case of Paget's disease is also modified by their discovery. When the lesion is still superficial and non-ulcerated, it should be treated with chloride of zinc, followed by mercurial plaster; or with iodoform. It is possible by these means to bring about a cure. When there is ulceration, but not much induration, the surface should be energetically scraped and covered with antiseptic dressings. When a nodule is formed, or there is marked induration under an ulcerative surface, the disease must be cut out.

Tumors of the Scalp.—A. Poncet (*Rev. de chirurg.*, 1890, xi, 244) reports a rare case which has come under his observation in which the head of the patient was covered with a great number of tumors—about sixty in all. They were so numerous that their edges touched. They varied in size from that of a pea to that of a tomato, and were of irregular form, though often round. Here and there they were ulcerated. They were freely movable and here and there pedunculated. In color they varied from that of the normal skin to a violaceous hue. Upon them there was scarcely any hair, while between them there were thick tufts. They were hard to the touch and not fluctuating to pressure. The head gave a nauseous odor, due to a mixture of epithelial and fatty fermentation. There was enlargement of the submaxillary glands. Similar tumors were located upon the body in the dorsal region. These tumors appeared when the man was twenty-one, and ulcerated only upon injury. The man was fifty-three years old and in excellent health. His occupation was that of a sawyer, and the tumors are supposed to have originated in the sebaceous glands, to have been excited by injury, and to be of the nature of Billroth's cylindroma, a species of sarcoma. A number were excised and showed no tendency to return.

The Coincidence of Psoriasis and Syphilis is not so very infrequent. Neumann says (*Wien. med. Woch.*, xl, 1890, 257) that when the two diseases occur together, the diagnosis is made by watching the lesions for the development of a darker shade of red than is seen in psoriasis; by the effect of treatment, an antisyphilitic plan curing the disease rapidly if syphilis; and by the microscopical examination, the round cells being pigmented in syphilis.

Electrolysis applied to the Initial Sclerosis as a Means for the Abortive Treatment of Syphilis is the attractive title of a paper by Peroni in the *Giorn. ital. del. mal. ven. e della pelle* for September, 1889. He believes that the initial lesion of syphilis should be regarded as a purely local lesion until there is some evident reaction on the side either of the lymphatics of the genitals or of the glands themselves. He recognizes the difficulty of making a positive diagnosis between the initial lesion and a chancre (soft sore), and he regards induration of the sore to be the most reliable symptom in differential diagnosis. Believing that the initial lesion is a purely local process, he thinks that he can abort the onset of syphilis by destroying the initial lesion. The best time for the operation is before any symptom of glandular or lymphatic infection presents, and when the sore has existed for less than seven days. The best method for destroying the initial lesion is first to disinfect the part by means of wrapping it completely up in cotton saturated with a solution of bichloride of mercury (1 to 1,000), and leaving it on for twenty minutes. The part is then anæsthetized with cocaine, and, when that is accomplished, the sclerosis is destroyed by electrolysis. To accomplish this he uses a diamond-shaped lance an eighth of an inch wide and a quarter of an inch long. This, attached to the negative pole of a galvanic battery, is thrust into the tissues at a distance of about three eighths of an inch from the edge of the sclerosis and to about half that depth beneath it. When the lancet is in place the current is closed and allowed to pass for from half a minute to six or seven minutes, according to the size of the sclerosis. In this way, if the patient bears the operation well, the whole ulcer may be destroyed at one sitting, this effect being shown by the sclerosis being changed into a whitish pultaceous mass, which may be moved freely without pain. The operation is at times followed by œdema of the part that may last a day or so. Under an antiseptic dressing the wound generally heals in a few days. Twenty-nine cases were operated upon in the manner described, of which twenty-one gave positive results. [A further report will be made by the author. It is to be hoped that in the mean time he will use a milliampèremeter, so that he may give us some approximately exact idea of the current strength he employs.]

The Treatment of Syphilis by Subcutaneous Injection of Mercurial Preparations.—Dr. Leloir and Dr. Tavernier, of Paris, having practiced this method of treating syphilis in all sorts of syphilitic cases during two years, now (*Giorn. ital. d. mal. ven. e del. pelle*, 1889, xxiv, 247) give a statistical report of their experience and a summary of their conclusions. In all they made 1,573 injections. Of these, 875 were of one part calomel to twelve parts liquid vaseline, a half Pravaz syringeful being thrown into the sacro-lumbar muscles, and repeated once a week; 642 were of the yellow oxide of mercury, prepared and used in the same manner as the calomel; and 56 were of "gray oil," consisting of twenty parts of pure mercury, forty parts of liquid vaseline, and five parts of the ethereal tincture of benzoin, of which a third of a syringeful was injected every ninth day. They found (1) that these injections acted specially upon the erythematous syphilide and upon the secondary cutaneous eruptions; (2) that the injections of calomel and of the yellow oxide, especially the first, often caused these eruptions to disappear with a surprising rapidity, or, as they named it, a "true brutality"; (3) that the calomel acts most intensely, and the gray oil least; (4) that all three are much more energetic in their effects than any internal method of medication, though much rougher; (5) that their action on syphilides of the mucous membrane, especially mucous patches, is very slight, and, even while the injections are being practiced, numerous mucous patches will appear; (6) that their action upon tertiary syphilides is very uncertain, as they very often resist the injections and have to be treated by inunctions and the local application of mercury. The principal *ineonveniences* from this method of medication are the following: 1. The local or radiating pain caused by them, sometimes most violent, and capable at times of preventing walking. This may last from one to nine or more days. 2. Paralysis of the lower extremities. 3. Vertigo and headache. 4. Eruption of mucous patches in the mouth on the fourth or fifth day after the injection. 5. A mercurial dermatitis about the point of the injection. 6. Mercurial stomatitis, often slight, sometimes severe and long-continued. 7. A simple or bloody diarrhœa some time during the interval between the injections. 8. Non-suppurating cutaneous tumors, sometimes filled with a reddish serum. The treatment met with much

opposition in hospital practice, many patients preferring to leave the hospital rather than submit to it. Relapses seemed to be more frequent and precocious in cases treated by this method than in those treated by mercurial inunctions. The calomel injections produced the greatest number of disorders. The gray oil is the most inoffensive, but also the least active. The practical deductions from their experience are: 1. The use of subcutaneous injections of mercury should be limited to the early eruptions on the skin. 2. They may be resorted to when it is necessary to produce a very rapid effect on these eruptions. 3. They are specially if not exclusively applicable to hospital patients, or to those who can remain in bed for a few days. 4. It is a good means for treating prostitutes. 5. Its action upon mucous patches is very bad. 6. It does not prevent relapses. 7. In many cases it fails to cure, and recourse must be had to inunctions. 8. It should not be used against the late syphilides except in those exceptional cases in which it is necessary to use mercury internally at the same time with its local use and the administration of the iodide of potassium. 9. It is contra-indicated in cerebral and spinal syphilis, in visceral syphilis, in pregnant women, and in infants. The only advantage of the method is the rapidity of its action. But this advantage is more than balanced by its inconveniences.

Miscellany.

Maltine and Sterilized Milk.—In an editorial the Cincinnati *Lancet-Clinic* for July 5, 1890, says:

The heat of the last two weeks has been remarkable as occurring so early in the season, it being very rare indeed for fatal sunstrokes to occur in the first summer month. More than a score have already taken place in this city, while the news of the daily press informs us of a similar mortality in other cities and towns, while even those who live in the country are not exempt from the fatal effects of the sun.

Reports of sunstroke are usually of the heat-effects on adults, while the direct and indirect effects on the infant population are many times as great. Too often their main nutrient, milk, has become tainted or poisoned from the absorption of germs and gases, making of it a dangerous article of food and productive of summer enteritis or other trouble that leads to a fatal termination.

At this time of the year it is a good plan to have all milk sterilized as soon as possible. This is a very simple process, and consists of putting the milk in a clean bottle, loosely corking with a clean, new cork, and then placing the bottle in a vessel of water, and heating it slowly to the boiling point, this temperature being coutinued for forty-five minutes; then tightly cork the bottle and set it in a cool place until needed for use.

The nutrient properties of the milk are not destroyed, or even weakened, by this process, but for most persons it is more easily digested and is more nourishing.

Babies, children, and adults, in hot weather, should live as much as possible in the shade, where there is the freest possible circulation of pure air. Long and frequent cool baths for infants are very conducive to their health and comfort. There is nothing like a long cool bath to relieve the discomfort of prickly or summer heat, following this with a little anointing of the creases of the skin with cold cream, vaseline, or fresh lard.

In cases of looseness of the bowels, a few doses of the ordinary chalk mixture will usually furnish the desired relief. This should be given in tablespoonful doses and after every stool. Where there is a weakening of vitality, with very great propriety and advantage teaspoonful doses of maltine may be added to the sterilized milk, the diastatic power of maltine being capable of rendering soluble and digestible any starchy food that may be in the stomach. Starch foods, such as Irish potatoes and breads, have often been regarded as the immediate and irritating cause of infantile enteric disorders. In part this may be true, and yet these starch foods were the very ones the lacteals and absorbents were crying for and needed to stay the waste that was going on with fatal rapidity.

Right here the inestimable value of maltine, with its diastatic solvent properties, is quickly made manifest in changing the character of the discharges and causing an irritant factor to become one of nutrition; given in sterilized milk, the benefit of both is obtained.

In the city it is a good thing, in every possible case, to send the mother and infant out to the parks and suburbs for one, two, or three hours after sundown. The car ride is easy, while a shawl or other garment spread on the grass will afford a genuine relief and change from the mother's lap or cradle.

A little instruction from the family physician to his patrons in these simples may be the means of saving many valuable lives; nor should the physician take it for granted that his clients are informed in such matters, for very intelligent people sometimes are very ignorant of the plainest hygienic rules. This is especially the case in regard to the care of very young children. We recently saw an illustration of this in a very intelligent-appearing mother, who did not even know how to hold her infant in positions of comfort to the babe and ease to herself. Even in such matters as this the doctor may give wholesome advice.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

SURGICAL MYCOSES.

A CLINICAL LECTURE, DELIVERED AT THE PHILADELPHIA HOSPITAL.

By ERNEST LAPLACE, M. D.,

PROFESSOR OF PATHOLOGY AND CLINICAL SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA; VISITING SURGEON TO PHILADELPHIA HOSPITAL, ETC.

LECTURE I.

REPORTED BY WILLIAM BLAIR STEWART, M. D.

I WISH to draw your attention this morning to a number of cases that should not be considered singly—not this, that, and the other affection—but a condition that I wish you to consider under the name of surgical mycosis.

Mycosis is an affection due to the development in the tissues of some fermentative agent, fungus, or germ. In surgery we deal mostly with diseases of the exterior of the body, such as tumors, enlargements, or solution of continuity; enlargements that remain as enlargements for a long time, or else, by suddenly ulcerating, turn into an ulcer or solution of continuity. To specify and start a list of surgical mycoses, I will speak first of tuberculosis.

Tuberculosis, as you all know, until 1882 was something vague in the minds of pathologists, and not until Koch established the identity of tuberculosis of the lungs and other organs did we begin to understand the disease.

This patient comes to us with an affection of his joints. On close physical examination, it was found that the apices of his lungs were infiltrated, and we know he is tuberculous. His elbow and wrist are swollen and infiltrated with a substance that is cheesy, and, on probing, it was found that the cartilage of the joint had disappeared and dead bone was found. The cheesy substance is so typical that we know it is the result of tubercular degeneration, so that there is no reason why we should not pronounce this a case of tuberculosis of the elbow joint, and if we would apply a therapeutic measure it would require amputation.

I will show you all the cases I have this morning at once before operating, and demonstrate to you the great similarity that pervades their ætiology. The next case is one of cheesy degeneration of the cervical glands. The same process has taken place in the glands of the neck, and we have that cheesy product of tuberculosis. Here you can see the sterno-mastoid muscle running across this opening, and all around it is the same cheesy material that you saw in the former case. The neck is infiltrated. I want in this case to call your attention only to the identity of the process.

Next is a case of carbuncle that is nearly well, but is typical enough for illustration. You all have seen a carbuncle and you know how large, painful, and ill-defined it is, and when it approaches suppuration a crucial incision is needed. You notice several so-called openings, or heads, from which comes yellow, cheesy matter. There is discoloration around it and it is hard and boggy. This pus abounds with germs which are named *Streptococcus pyogenes aureus*, *Streptococcus pyogenes albus*, *Streptococcus pyogenes citreus*, and *Bacillus pyocyaneus*.

These are found in ordinary furuncle, but, for some reason or other, several furuncles form in the same place, and, when so formed, we call it a carbuncle.

Next are two cases of pronounced epithelioma. I wish you to remember the appearance of the tuberculosis of the glands and arm and draw the analogy between epithelioma and tuberculosis of the skin. Here is a large epithelioma. This patient had a small wart that was removed a year ago but returned. The growth is in a rapid state of development, is movable, and does not affect the superior maxillary bone. What I want to draw your attention to is the fact that here is a fungus-like growth that develops rapidly and is recurrent. It has recurred in this case just as tubercular growths recur when they have been improperly removed.

This is a patient whose left cheek I wish you to see first. There is a tumor, large, adherent, non-fluctuating, and a slight ulceration near the base. If you saw this tumor alone you would be puzzled as to a diagnosis between syphilis, tuberculosis, and cancer; but, in view of this patient's history, we are warranted in diagnosticating it on first sight. The tumors of both sides of the face are of the same nature—epithelioma. The point of interest is that here is a tumor that bears a close resemblance to tuberculosis, since it has involved the same tissues as tuberculosis and looks like it. May we not be led to think it may be caused by something analogous to the cause of tuberculosis?

Here is a case of senile gangrene. You find the arterial circulation perfect to the middle of the limb. It is a case of soft gangrene and the obstruction is in the veins. Gangrene is death of the part due to a cutting off of nutrition—the circulation. The leg presents an emphysema below due to sulphureted hydrogen and carbon-dioxide gas that are the result of the fermentative process in the limb. Why does it putrefy? Because vitality has disappeared by a cessation of circulation. This alone would not cause putrefaction, but we must have the germs present to destroy the tissues or cause this suppuration. You know that if we take a piece of meat, boil it and can it, it will keep for a long time and not spoil; but the dead tissues of this leg, by exposure to the atmosphere, have been infected by germs, and the putrefaction called gangrene was the result. In this case, then, there was an arrest of the circulation and then an infection by germs. This is another illustration of a surgical mycosis.

The next case is one in which the diagnosis is not perfectly clear, and must be treated symptomatically until we find the true ætiology of it. Here is a woman who came into the wards two weeks ago and presented a tumor of the neck that came rather suddenly and appeared to be intimately connected with the thyreoid body and which would rise and fall with the act of deglutition. In a few days the growth limited itself and spread to the right, and did not rise and fall with deglutition. Yesterday it presented symptoms of acute inflammation and was highly fluctuating. Although I am not positive as to a diagnosis, yet I am positive that there is fluid here, owing to the acute inflammatory pro-

eess, especially on the surface. Whatever it is, it is due to a rapid proliferation of cells of one of two kinds—either it is filled with pus, or else there is a rapidly developing epithelioma of one of the lymphatic glands, and in this case we would find a growth consisting of epithelial tissue, giving a soft and fluctuating appearance that you find in this condition.

Before we operate on this patient I wish to dilate on the idea that I have brought before you of arranging such facts under a heading that refers them to their ætiology. It is only in that way that we can put surgery on a more scientific basis, by reasoning from an ætiological standpoint rather than from a clinical aspect, as many diseases have the same ætiology, and the same mycoses will demand the same treatment.

Such consideration has only been possible since Koch demonstrated the tubercle bacillus. Then came Rosenbach with the discovery of the germs of suppuration and, necessarily, the cause of ulceration, for there is a disintegration of the skin over the place that has suppurated. Other experiments were made on ulcerations that were not of this form, until Israel, who came in 1884 and described *actinomycosis*, which is the so-called ray or star fungus disease and exists in the bovine species. The fungus enters the mouth and alimentary tract, and is carried by the blood and develops on the face, or on the surface of the thoracic cavity, and causes infiltration and ulceration, in which these germs have been found. Just as these germs have been found to cause suppuration, so these ray fungi have caused this disease of actinomycosis, also a surgical mycosis.

Anthrax is the next affection due to a peculiar germ. It is also called malignant pustule, or splenic fever of animals. Butchers and tanners are especially liable to it. They have a wound on their hand which becomes infected by this peculiar germ and develops the disease malignant pustule, which is very dangerous.

As to syphilis, you may consider it under the same heading. Lustgarten described the bacillus of syphilis, but it has not been positively demonstrated.

Although complete researches have not been made as to the cause of cancer, yet the researches of Scheuerlein are sufficient to establish the presence of a germ—the same germ for epithelioma and cancer. In order to prove a germ we must subject it to four tests:

1. We must find the same germ always present in the same affection.

2. The germ must be isolated and grown.

3. The germ must be inoculated and produce the same disease.

4. The germ must be found the same after inoculation.

It has been found that the rat is very susceptible to cancer, and we can inoculate it and cause a growth like cancer. Finally, you see what progress has been made in the ætiology of surgical affections, simplifying the matter and bringing it down to irritants in the body. Let us hope that the coming generation will make as great improvements in the treatment as the past has in the ætiology of surgical mycoses.

Original Communications.

A REPORT OF SEVEN OPERATIONS UPON THE KIDNEY.*

By WILLIAM D. HAMILTON, M. D.,
COLUMBUS, OHIO.

Renal surgery may be said to have received its first legitimate impetus in 1869, when Simon, of Heidelberg, relieved a patient suffering from ureteric fistula by removing the kidney of the affected side through a lumbar incision. The growth of this phase of abdominal procedure has been rapid from that time to this, and certain operations on the kidney are looked upon to-day as conservative undertakings. No paper, however brief, would be complete which omitted the name of that master of renal surgery, Mr. Henry Morris, of Middlesex Hospital, London; while the valuable contributions of Thornton, Tait, Hahn, Bennett May, Lange, and many others, deserve prominent mention in this connection.

The cases forming the subject of this paper are six in number, and are all that have come under the observation of the writer in the last three years in which an operation was allowed. There were two nephrorrhaphies, two nephrotomies, two nephrectomies, and one incision, with drainage, for perinephric suppuration in a case of movable kidney. In a paper read before the Ohio State Medical Society at Toledo, in June, 1887, a successful nephrectomy, after preliminary exploratory incision, was described. Hence it will be seen that nine operations on the kidney comprise the entire experience of the writer in this department of surgery, and that, although in three instances the kidney was removed, all the patients recovered.

Judging from this list, the observations of Mr. Greig Smith and others would seem to be correct:

1. When the kidney is not greatly enlarged, lumbar nephrectomy is easier and safer for the general surgeon to perform than the anterior operation.

2. A preliminary nephrotomy lessens the danger of nephrectomy.

Absolute cleanliness was observed. A bath and laxative preceded the operation in each case. The bowels were thoroughly emptied, a simple diet having been persisted in for some days. At the time of operation the loin was scrubbed with soap and water, washed with ether, and afterward with a warm sublimate lotion. Antiseptic irrigation was freely resorted to. In the preparation of hands, instruments, sponges, and everything else that could influence the result, as great care was exercised as though the peritoneal cavity were to be invaded. I would here emphasize the great importance of having the patient covered with warm woolen blankets, except about the field of incision. In this way the pleura is less liable to give rise to trouble by becoming inflamed after operation.

Case I. *Tubercular Suppuration of the Kidney; Nephrotomy; Nephrectomy Three Months Later; Recovery.*—Mrs. K., a stout

* Read before the Northern Ohio Medical Society, June, 1890.

German woman, aged twenty-two; residence, Colnmbns; married one year, and had never conceived. Has always menstruated regularly. In childhood she was treated snccessfully for hip disease, and, although she limps slightly, has nothing else to show for her early misfortnne. She had never had pain so intense that it could properly be called renal colic. Examination showed the lnngs to be healthy. For several months prior to her admission to the hospital she had been losing flesh and strength. It was on account of frequency in urinating that she consnlted a physician. Every such act was attended with scalding pain. At night her sleep was invariably interrnpted in this way. Her appetite was poor. For fonr months she had had chilly sensations, a rise of temperatnre, and occasional night-sweats. During the few weeks in which she was nnder observation her pulse was never less than 100, and her temperatnre ranged from 100·5° to 102·7° F. A dnll, aching pain had existed in both loins, especially in the right one, during the previous few months, and was subject to occasional exacerbations. She had observed that her nrine, usually cloudy during her illness, was clearer and less in qnantity when the right lumbar pain was most intense. A sandy sediment had been visible a few times. Blood had never been seen in the nrine. Riding, walking, or any sndden movement always hurt her. Aside from such aggravating causes, she suffered more in the morning than at other times. Pressure over the left loin caused no inconvenience, but on the right side was distressing to her. No enlargement of the kidney or tumor was discernible through the thick parietes.

Examination of the urine showed that the reaction was invariably acid and that pus was always present. Neither casts nor tnbercle bacilli were ever discovered. Sonnding the bladder indicated the absence of stone. Vesical irrigation with a warm solntion of boric acid gave temporary relief.

Diagnosis.—Pyelitis, with possibly stone in the kidney.

Operation, October 13, 1888.—Ether narcosis. Costo-iliac space was very short. A hard pillow having been placed beneath the sound side, thus putting the right loin on the stretch, an incision was made four inches and a half long, below and parallel to the last rib, terminating two inches and a half from the spine. It was extended for a distance of an inch vertically downward at its inner end. The fatty capsule was normal and not strongly adherent. The kidney, enlarged to several times the ordinary dimensions, was lobnlated and fluctuant. Exploratory pnncture revealed an inodorous mixture of pus, urine, and serum. An incision into the renal substance permitted the free discharge of this fluid. Carrying in the finger, the organ was found to be converted into a sacculated tnmor, the various compartments of which contained fluid. No stone was found. Thorough irrigation with bichloride solution was employed, a rnbber drain was inserted into the kidney substance, and the wound was closed with silk stitches. Her convalescence was nneventful, the wound healing except in the track of the drainage-tnbe, where urine and pns continued to discharge.

There was an entire subsidence of pain and hectic, and the nrine voided in the natural way became perfectly clear and was free from albumin. She grew stronger, her color improved, and but for the presence of the fistnlous opening, her health would have been perfect. She was advised to have the kidney removed in order to get rid of this source of irritation and annoyance; and accordingly re-entered the hospital.

Operation, January 19, 1889.—Incision through the old cicatrix. The various anatomical layers were matted together so as to render them difficult of recognition. Owing to the thickness of the parietal fat and the density of the scar, the isolation of the kidney was by no means easy. The proper capsule having been incised, the fingers were used in separating the adhesions between capsule and kidney nntil finally it was generally freed. At this point the greatest obstacle to the completion of the operation was encountered. Although diminution in size had supervened as a result of the nephrotomy of three months before, the great depth at which the pedicle had to be secured, and the fact that fnlly the npper two thirds of the organ lay behind the projecting rib and intercostal space, added to the delay, and frequent efforts to ligate the pedicle resulted in failure. Finally a wire écraseur was passed around it, and included in its grasp vein, artery, ureter, and a small amount of renal tissue. In order to deliver the kidney it was cut away piecemeal, the constrictor being tightened during the dissection. Thorough irrigation followed and the écraseur was left in the wound. Considerable pain marked her convalescence. There was very little fever and the urine remained clear. The instrnment was tightened from day to day as the pedicle loosened, and it came away four weeks after the operation. Anodynes were employed to snbdne the localized pleuritic inflammation that followed. She was discharged a few days later, and has since remained in good health. A small sinus lasted for some months, but finally ceased to give rise to annoyance.

Case II. *Supposed Case of Renal Calculus; Preliminary Exploratory Incision; Temporary Relief; Recurrence of Hæmaturia; Nephrectomy; Recovery.*—Miss J. P., aged twenty-six; residence, Delaware, Ohio. Had been an invalid for five years and a half, dnring the latter part of which time she had painful mictnrition as often as fonr or five times honrly, night and day. She had several attacks of renal colic, four of which were very severe. The worst one had occurred just prior to her admission to the hospital. For two years previous to operation she had never been free from hæmaturia. Pain was always referred to the left loin, which was tender on pressure. although there was no sign of enlargement. She was reduced in flesh and weighed eighty-five ponnds. She was a bedridden invalid most of the time. Her father had died of phthisis pnlmonalis, and she had incipient disease of the same character. Her last attack of renal colic, in April, 1889, continned a week, was very severe, and a large quantity of clear blood was passed. The urine nsnally contained blood finely mixed with it. No pns, casts, albnmin, or sabnlous matter could be detected. Tenderness in the left loin was so marked that she flinched, even when nnder ether, if pressure was applied to that part of the body. Sounding for vesical calculus yielded negative results, and a careful use of the instrument failed to discover any papillomatous tumor or other irregularity in the wall of that viscus. Examination by the rectum and by conjoined manipulation prodnced like negative results. Her alvine evacuations and menstrnations were regular and presented no peculiarities. In the previous year she had habitually observed that the hæmatnria was aggravated dnring the premenstrual week. All attempts to relieve this condition hy rest and medication failed. Urethral dilatation and antiseptic vesical irrigation likewise were of no avail. Something must be done to relieve the continual drain upon her strength. An exploratory left lumbar incision was advised and was performed by Dr. Charles S. Hamilton. The usnal plan was adopted. The organ was found upon exposnre to be slightly above the average in size, smooth, and free from indurations in its substance. All parts of it were carefully examined with the finger. A systematic series of punctures was made, bnt no abnormity was discovered. The wound was closed, a drain was inserted, and healing was prompt. For a week there was entire cessation of the hæmaturia and very little pain, the quantity of urine voided in twenty-four hours remaining the same as before—*i. e.*, from one to two pints. The fact that a snbsidence of symptoms had taken place for the first time in a year after extensive puncture of the left kidney was

regarded as strong presumptive evidence that the organ of that side had an important relation to the hæmaturia.

Furthermore, the bleeding, pain, and scalding in passing water had returned with redoubled intensity, and greatly discouraged the patient. She was advised to submit to a second operation, and if, after incisions into the renal substance, no explanation of the hæmorrhage could be found, nephrectomy was to be done.

Operation, May 15, 1889.—Having fresh in mind the difficulties encountered in previous nephrectomies, I followed the very valuable suggestion of Lange by resecting the twelfth rib, so as to give increased room for the necessary manipulations. The incision through the former cicatrix was easily accomplished, as union was not yet firm. An extension of it at an acute angle, joining the inner end of the former one, resulted in the formation of a V-shaped flap. The muscles were well cleared away in the dissection toward the median line, which greatly facilitated the operation. A coarse silk ligature secured the pedicle *en masse*. Her convalescence was tedious. She had no hæmaturia, voided healthy urine freely, and gave no anxiety on account of ugly renal symptoms. Owing to the free exposure of the pleura, the unavoidable chilling of the left side from having it uncovered during the operation, and the cooling effects of evaporation following irrigation, she had a sharp attack of pleurisy with effusion. This, however, finally yielded to appropriate measures, the wound healed kindly, and she has gained in flesh and strength. She is now in good health, weighs one hundred and nine pounds, and is filling a responsible clerical position.

This case is one involving rather unscientific interference in that the kidney is apparently healthy. It involves a startling and apparently unjustifiable empiricism. The explanation of the hæmaturia and pain I am unable to give. The supposition that a small calculus became lodged in the ureter and escaped detection may explain it. Again, early tubercular involvement might account for it. The justification would seem to lie in this fact, that a young woman who had been a confirmed invalid for three years has been restored to health and usefulness. It may well be added that an operator should feel better satisfied when, in addition to having his patient get well, he is able to indicate clearly the pathological reason for the course pursued. She has had amenorrhœa since the last operation, and it is hard to convince her that the uterine appendages were not also removed.

Case III. *Movable Kidney; Nephrorrhaphy; Recovery.*—Mrs. N. B., aged thirty, sent by Dr. C. F. Coyle, of Galion, Crawford County, Ohio, had had both menstrual and premenstrual pain for nine years. Had soreness in the left inguinal region. The most severe pain was that which preceded menstruation for several days, and was of a bearing-down character. The effort to walk any distance caused pain. A copious stool was attended with soreness in the region of the left kidney. Examination showed a tumor descending on the left side to a level with the anterior superior spine when the patient stood upright. It was freely movable, and, if the horizontal posture was assumed, it could readily be forced into the loin. On October 5, 1889, an incision was made below the last rib, similar to that described above. The fatty capsule was found to be very loose. The proper capsule was incised. Silk stitches were made to include skin, subcutaneous structures, and both capsules, the fatty capsule being pulled taut in such a manner that the excess lay outside the wound. No febrile disturbance ensued, and healing by granulation was the result. The organ has remained in its proper place, and she is free from symptoms that could be attributed to the pathological condition alluded to.

Case IV. *Suppurating Kidney; Nephrotomy; Recovery.*—Mrs. G. T., of Columbus, was referred to me by Dr. N. R. Coleman, who had diagnosticated a suppurating left kidney. Was twenty-seven years old, had been married nine months, and her menstrual life had been a normal one. There was nothing pointing to the existence of pelvic suppuration. In her sixth year she had severe pain in the left side, always aggravated by riding or jolting. The only period of her life in which she had enjoyed entire immunity from suffering was that extending from the twenty-first to the twenty-fourth year. She had always been subject to renal colic. With the exception of the interval alluded to, she never passed a month without one such experience. The pain started in the loin and followed the ureter. She estimated that forty attacks had occurred in the last three years, and they had been steadily increasing in severity. Furthermore, pus had been observed for the first time in the urine, and had increased in quantity until it became very profuse. No stone or sabulous matter was ever visible.

The average amount of urine excreted in twenty-four hours, when Dr. Coleman first saw her, was one quart, and half of it was purulent. Reaction always acid. Vomiting had never taken place.

The weight of the patient was seventy pounds, whereas formerly it had been one hundred and thirty. It is uncommon even in advanced phthisis to see greater emaciation. The left hypochondrium and loin were exceedingly tender and quite prominent, especially at a point an inch behind the midaxillary line in the center of the costo-iliac space. Upon palpating the left loin, a hard, tender, rounded, smooth swelling filled the upper part of this space and encroached upon the hypochondrium. It was all the more apparent on account of her extreme emaciation. The same tests applied to the other side elicited an apparently healthy condition. The average pulse was 90, temperature 99·37°. Diagnosis confirmed. Nephrotomy. On November 19, 1889, an incision in the most tender part of the loin found the fatty capsule tough, indicating inflammatory changes. A needle brought pus. The knife, being inserted, opened a large abscess cavity, the contents of which were very foul. A pint and a half of this material was discharged. The kidney was extensively disorganized. After thorough washing out with a weak sublimate solution and the insertion of a rubber drainage-tube, the wound was closed. No untoward symptoms were present, and she got well rapidly. Her appetite became good and she took on flesh at such a rate that she gained sixty-three pounds in six months. The urine is normal, she is free from pain, and, aside from the fact that she has an inoffensive sinus, her health is excellent.

Case V. *Movable Kidney; Nephrorrhaphy; Cure.*—Mrs. E. R. K., of Plain City, Madison County, Ohio, was sent to me by Dr. J. H. Gardner, of that place, with the above diagnosis. She was twenty-seven years old, had been married five years, had one child three years old, and had miscarried at the sixth month soon after marriage. She dated her disability from the latter event. Her menstruations have been regular, and for seven years had been painful. During the last six months she had dragging pain for a week prior to menstruation. Beginning in the right loin and following the direction of the ureter of that side, there was continual soreness, aggravated at times by standing or walking. A smooth, ovoid tumor could be detected on the right side. It was freely movable between the upper part of the right inguinal and the lumbar regions. Its shape was that of the kidney. A singular fact in her case was this: that lying on the back frequently caused her pain to increase, and at such

times standing erect gave her relief. In the last two years and a half she had had twelve attacks of severe pain in that part of the abdomen indicated. The urine was normal. There was no nausea. The diagnosis of movable kidney was confirmed, and nephrorrhaphy was done January 25, 1890. The same plan was adopted as in Case III, the skin, fatty, and fibrous tissue being secured with silk stitches, the fatty layer having been pulled taut while the redundant tissue was allowed to remain on the outside. Free scratching of the kidney was resorted to, so that an abundant plastic exudate would be thrown out. In this, as in Case IV, Mr. Morris's suggestion of stuffing the wound lightly with gauze was used and with good effect. Healing by granulation resulted, and there was an entire absence of unpleasant symptoms. This patient has unquestionably been entirely relieved, so that she now enjoys perfect health. She has gained fifteen pounds in weight.

Case VI. *Movable Kidney; Nephrorrhaphy attempted; Perinephric Suppuration found; Incision and Drainage; Failure to find the Kidney; Recovery; Improvement.*—Mrs. C. A. W., of Columbus, a delicate woman, aged fifty. married twenty-one years, had four children, the youngest ten years old. She had not yet ceased to menstruate. Ten years previously, after the birth of the last child, she had typhoid fever followed by severe pains in right foot, on account of which she wore a supporting shoe for two years. This was followed by severe pains in the back, for which a plaster jacket was put on and worn for three months with some relief. One year prior to admission she had a relapse and her health became poor. She had rigors, loss of appetite, flesh, and strength. Micturition occurred fifteen to twenty times in twenty-four hours, accompanied with burning pain, referred to the neck of the bladder. When standing or walking, her form was stooped. A movable lump descended to within an inch of the level of the navel. She had pain in the right kidney and ureter, and was only comfortable when lying on that side.

Specific gravity of urine, 1·020. Traces of albumin. Diagnosis, movable kidney.

Operation, February 18, 1890.—The usual lumbar incision for nephrorrhaphy was made. Opening the loin, a large quantity of inoffensive pus escaped. It resembled thick mayonnaise dressing. The kidney could not be found. Irrigation was thoroughly carried out and a drainage-tube was inserted. Her recovery was tedious, but was not marked by intensity of symptoms. She was discharged from the hospital four weeks later. She has gained several pounds in flesh, and can stand and walk erect without pain. The kidney can now be located where it is firmly fixed nearly as high as it should be. She feels well as long as the sinus discharges. There is now about twelve per cent. of pus in the urine.

In cases where perinephric suppuration attends a movable kidney, failure to find the organ at the time of operation has occasionally resulted. In this case the improvement in position is probably due to contraction of the abscess cavity—*i. e.*, the distended fatty capsule. The radical operation of removal may yet have to be done.

A New Alkaloidal Reagent.—"M. Brociner finds that sulphotellurate of ammonium in solution in sulphuric acid gives characteristic colors with certain alkaloids. Thus with digitaline it gives a reddish violet tint, gradually becoming more intense; with chelidonine it gives at first no reaction, but in a few seconds a green color becomes apparent, becoming more pronounced in about four minutes; with apomorphine it gives a violet color; with narcotine a fugitive rose tint; and narceine becomes first yellow, passing to a dirty green, finally turning to violet."—*British and Colonial Druggist.*

A CASE OF SEVERE HÆMATURIA;

NEPHRECTOMY BY DR. McBURNEY.

*RECOVERY.**

By F. TILDEN BROWN, M. D.

C. G., twenty-six years of age, five years married, three children. No miscarriages. Family history markedly gouty. Health previous to the first attack of hæmaturia had been good, except for two periods of marked and somewhat critical anæmia. The first of these occurred two years before marriage, the second a year later.

In March, 1888, when her second child was four months old, appeared the first recognized trouble with the right kidney, and attributed to over-exertion in caring for her child. The symptoms as now recalled were sudden and marked hæmaturia; pain in the right kidney region, radiating to the distribution of the anterior crural nerve below Poupart's ligament; fever reaching at the highest 104° F. Her attendant at this time, a man of great experience and marked ability, diagnosticated the rupture of some renal vessel. Acute pain and hæmorrhage disappeared rather suddenly at the end of five days. The only subjective sequence was a sense of dull pain in the right side and thigh when she was tired. Examination of the urine on one or two occasions after this attack is said to have shown considerable pus. However, the patient felt well enough to dispel any thought on her own part of chronic disease.

The second attack occurred in August, 1888, when she was two months pregnant. As the patient made a sudden jump and strain to seize a child from a wave on the sands she experienced a sharp pain in the right side.

On reaching home twenty minutes later she found her urine heavily charged with blood. This attack was characterized by a repetition of the symptoms of the first, with the exception that the fever was not so high. In this, as in the first attack, the repeated use of a stiff catheter was necessary, not as it is ordinarily used, but to punch back the blood-clots blocking up the sphincter vesicæ and preventing micturition.

Diagnosis by a different physician, renal calculus; and treatment in accordance was followed by rather sudden recovery from acute symptoms in about the same time as was the first attack.

Third attack, October 26, 1889, at which time I first saw the patient professionally, and learned that an hour before at the first morning urination she noticed a marked hæmaturia, and at the moment thought it a menstrual manifestation, which was welcomed because there was some reason to believe herself two months pregnant; and for the dissipation of this she had recently resorted to the hardest riding, domestic fatigues, and Turkish baths. The night before, on going up stairs, she felt some pain in the back, but the night had been passed free from any discomfort. A second micturition shortly after the first was more heavily charged with blood and attended with some pain, as large blood-clots passed the urethra. Synchronously with the appearance of hæmaturia, pain was first felt in the right side. This pain was continuous, but at times much augmented, with an extension of the painful area to Poupart's ligament and some in the leg below. Clots collecting in the bladder were already troublesome in retarding urination.

Physical examination of the suspected region showed tenderness on pressure between the twelfth rib and the crest of the ilium. Antero posterior palpation with one hand compressing this region and a little lower was equally sensitive. No tumefaction was appreciable; percussion was normal. Vaginal

* Read before the American Association of Genito-urinary Surgeons.

examination relative to ureter and bladder was negative. Temperature (sublingual), 100·2°; pulse, 76.

The examination of urine showed specific gravity 1·030; color, deeply stained with blood evenly distributed. Reaction *very* acid; sediment, moderately copious.

Microscopical Examination.—Blood-corpuscles in great quantity; pus-corpuscles in quantity; great numbers of a long rod bacillus; no crystals of any kind.

Chemical Examination.—Albumin, one eighth bulk.

Diagnosis.—Renal calculus. Treatment was instituted to meet the prominent indications—viz., pain and hæmorrhage.

For the next four days the patient's condition continued much the same, except that exacerbations of pain were more severe. The afternoon temperature reached a higher point, 103°. Clots collecting in the bladder were now more painful to pass. The patient at each micturition was compelled to resort to the punching process with the silver catheter. Any movement in bed caused distress in the kidney region, and palpation of it showed increasing tenderness. Many of the clots were as large as and resembling a poached egg, while several, thicker than a pencil and five inches long, were evidently casts of the ureter.

At this time Dr. McBurney was called in consultation, the result of which, after careful examination of the patient and a review of the history, was to support the diagnosis, at the same time advising a continuance of the expectant plan of treatment, until, as the previous attacks led one to hope, an early and sudden cessation of the hæmaturia would permit a clearer appreciation of the renal affection to be gained by repeated urinary analysis. Fluid extract of ergot was added to the treatment.

During the next five days the patient had been constantly approaching a more serious condition. Anæmia was now very marked. Nausea and vomiting had seriously interfered with taking the requisite food. Increasing pain was demanding morphine in greater quantity. Clots had so distended and irritated the urethra that every micturition was a source of anxiety. Ergot had seemed to increase both renal pain and hæmorrhage; in consequence it was discontinued after two days. Twice these symptoms—pain and hæmaturia—had for a short time very encouragingly diminished, but, without appreciable cause, returned in a few hours as bad as or worse than before. At this juncture the patient's condition seemed to me to demand surgical interference. The patient craved it, and her family, realizing that this attack was so much more serious in every particular than former ones, were equally solicitous.

Dr. McBurney was asked to perform nephrotomy. To this he agreed, making the appointment for two days later, November 5th, should no improvement be reported in the mean time.

On gross examination the two specimens of urine passed just before operation were but faintly blood-colored. Notwithstanding this, in the face of the previous disappointments, it was not deemed advisable to credit this suggestion as permanent.

The total quantity of urine passed during the twenty-four hours before operation was thirty-six ounces.

Operation.—All the evidence pointed strongly toward the existence in the kidney of a calculus, and the rapidly failing condition of the patient called for immediate and energetic measures. The operation was begun with the intention of exposing the surface of the kidney, in order that the organ might be thoroughly searched. After every antiseptic precaution had been taken, a four-inch incision was made just below and in the line of the last rib on the right side. The outer edge of the kidney was readily exposed, and then the posterior surface laid bare. The operator failed to detect any foreign body in the pelvis of the kidney. On the posterior surface in the lower half a small, hard, elevated spot, perhaps a quarter of an inch in diameter, led to the belief that a calculus might be imbedded in the substance of the organ at this point. A round needle was thrust first into this spot and then into many other parts of the kidney without result. The anterior surface was then uncovered, and by bimanual examination a rapid but thorough search was made, which was equally unsuccessful in discovering a cause for hæmaturia. Further loss of time in the search for calculus seemed unwarranted in view of the already prostrated condition of the patient. No other means of putting an end to what would certainly have been a fatal hæmorrhage remained for consideration but the shutting off of the blood-supply, which could only be accomplished by the extirpation of the kidney. This plan was not difficult to carry out, and was executed as rapidly as possible. The kidney was still more completely enucleated from its fatty envelope and drawn well into the wound, and, as time was all-important, the vessels and ureter were included in a single heavy catgut ligature, at as great a distance from the kidney as possible. The kidney was then cut away. No hæmorrhage followed, and the wound was closed with deep and superficial sutures, a large drainage-tube being introduced at each extremity of the wound. A heavy antiseptic dressing was applied. Although scarcely any blood had been lost during the operation, the patient was markedly shocked at its close, and required hypodermic stimulation and heat to establish reaction.

The subsequent report is condensed from copious notes. Every specimen of urine passed was measured, freshly bottled, numbered, and almost immediately examined at the patient's house, where I was constantly present for the ten days following and well equipped for this work.

November 6th.—For the first twenty-four hours after operation temperature averaged 102·5°, pulse 130, respiration 22; total urine, 23½ ounces.

The early part of this period was characterized by moderate shock. Afterward the prominent symptoms were nausea and vomiting; muscular twitching, especially during sleep; deep flushing of the face; a complete numbness in the right leg; at times free perspiration. The first urine was passed eight hours and a half after operation—in amount four ounces. It contained some blood, but not, as before, evenly distributed throughout the urine, as is the case when these fluids are mingled in the kidney. This urine then represented the new scanty secretion which was contaminated in the bladder by the blood-charged urine forced from the removed kidney just before or during the operation.

After this the urine was free from blood, except as found microscopically.

7th (second day).—Average temperature, 102°; average pulse, 128; total urine, 20½ ounces. The patient continues in the same condition, experiencing nausea, twitching, localized flushing, and sweating. Specimen of urine No. 8, passed at 11 A. M., was the first in which renal casts were found. The four following specimens showed epithelial and granular casts in increasing numbers, and albumin in increasing quantity, amounting at the most to one fifth bulk.

Dr. McBurney visited the patient to-day. The wound was redressed for the first time. It was in an absolutely aseptic condition, and showed union throughout its entire length close up to the drainage-tubes.

Owing to nausea, rectal alimentation has been given at times during the day.

8th (third day).—Average temperature, 100·2°; average pulse, 118; total urine, 21½ ounces. This appears to have been the most critical day experienced by the patient subsequent to the operation. Although the pulse and temperature are lower,

such other symptoms as constant nausea and vomiting, great restlessness, dryness of the skin, persistent muscular twitching, and for the first twelve hours diminished urinary secretion—all combined to cause alarm. Early in the afternoon infusion of digitalis is given *per rectum*. Hot poultices packed about the kidney, and a combined hot-air steam bath given in bed. To this the skin promptly responded, and sweating was continued, with few interruptions, for twenty-four hours. Besides which the urinary secretion was somewhat augmented.

9th (fourth day).—Average temperature, 99°; average pulse, 104; total urine, 19½ ounces. Patient passed a better night than at any time since the operation. Number of renal casts is much diminished. Quantity of albumin slight. Some nausea. No vomiting. Patient begins taking strophanthus, five drops every four hours.

10th (fifth day).—Average temperature, 100·4°; average pulse, 118; total urine, 18½ ounces. Albumin is again appearing in greater quantity. Casts with renal epithelium and a few blood-corpuscles are once more noticeable. The work thrown upon the single kidney is evidently embarrassing its functional power, and the entire organism acts in sympathy with its labored working. The wound is redressed. A slight suppurative condition is found about each drainage-tube, attributable, undoubtedly, to the copious sweating which had worked under the dressing, soiling it, and carrying septic material to the wound. Hereafter dressing of the wound was done daily.

11th (sixth day).—Average temperature, 99·4°; average pulse, 111; total urine, 20½ ounces. Patient's general condition slightly improved, especially the gastric symptoms, and is sleeping better. Albumin has again diminished. No casts found.

12th (seventh day).—Average temperature, 98·8°; average pulse, 107; total urine, 32 ounces. Patient is complaining of general discomfort. Occasional heavy pains in the back. Some ragged, decolorized clots or membranes were wiped from the vulva after micturition.

13th (eighth day).—Average temperature, 99°; average pulse, 103; total urine, 24½ ounces. Condition same as previous day.

14th (ninth day).—Average temperature, 99·8°; average pulse, 110; total urine, 28 ounces. As the recently anticipated symptoms of miscarriage became fairly manifest I lent all aid to facilitate the process, and at noon the fœtus with amnion and fluid came away intact. A uterine douche of carbolic-acid solution was given.

15th (tenth day).—Average temperature, 98·8°; average pulse, 102; total urine, 39 ounces.

For three days after this miscarriage the patient's condition was bad, notwithstanding her lower temperature and pulse-rate as well as a notable increased urinary secretion. The loss of blood was considerable and the utter prostration very pronounced. In fine, the patient's ultimate powers of resistance seemed to have reached their limit. An odor emanating from the entire body accentuated these other warnings. Fortunately, the digestive organs were now relieved of reflex uterine embarrassment and were able to retain and assimilate the really large quantities of food and drink forced upon them. Improvement was at once manifest. The elimination of urine on this day (November 18th) was sixty-five ounces. Henceforth convalescence was rapid and complete. A month later the patient weighed ten pounds more than ever before, and was said by her family and friends to look better than she had for several years. I have made regular urinary examinations at stated intervals during the seven months since this operation was done, and find an average report to be about as follows: Total urine in twenty-four hours, 47 ounces; specific gravity, 1·018; color, faintly opaque; reaction, over-acid; sediment slight.

Microscopical Examination.—Oxalate of calcium crystals; very few pus-corpuscles; always a number of rod bacteria.

Chemical Examination.—Never phosphatic or albuminous.

The kidney was submitted to Professor Delafield, whose report is as follows: "The mucous membrane of the pelvis of the kidney is considerably thickened and its free surface is somewhat roughened. The layer of epithelial cells is in place, but these cells are changed by post-mortem conditions. The muscular portion of the mucous membrane is considerably thickened. There is a growth of round-celled tissue beneath the epithelium, which in places forms small papillæ, and there are irregular infiltrations of the same round-celled tissue in the thickness of the mucous membrane. The same changes exist in the mucous membrane of the calices. Evidently there has existed a chronic pyelitis with the production of new tissue. From a mucous membrane altered in this way there could very well be a good deal of bleeding."

In conversation with Dr. Delafield he expressed the opinion that the original cause of this dangerous hæmorrhagic pyelitis was doubtless a calculus which had probably escaped among the large and numerous blood-clots which had been passed. But it is clear, from the whole history of the case, that a chronic condition had long since been established which was in itself capable of giving rise to fatal hæmorrhage, although the probable original cause—viz., calculus—had disappeared. Therein lies the chief interest of the case.

The literature of kidney operations recounts a number of cases where the symptoms of renal calculus existed, but where nephrotomy, needle puncture, and manual examination failed to verify the diagnosis. A number of these cases are reported to have been improved or permanently cured, seemingly, by the examination. It is impossible to think that these particular cases could have been similar to the one I now report, for, given a hæmorrhagic pyelitis and subject it to this treatment, it would of necessity result in the aggravation of all symptoms. In this connection I can not refrain from calling attention to the brilliant appreciation, on the operator's part, of the exigencies encountered in this case, for, when the calculus we expected was not found, the masterly conception and execution of an immediate nephrectomy in the face of very unfavorable conditions will receive the recognition it deserves, whereas it is now easy to appreciate that a so-called conservative step at this juncture would unquestionably have resulted in a rapid sinking of the patient from the hæmorrhagic state already existing and intensified by traumatic exploration.

It is conceded that there are few operations where cool and clear judgment on the part of the operator are so necessary as where, under certain or uncertain conditions, it must be decided whether or not to extend a nephrotomy to nephrectomy.

The effect of nephrectomy upon the remaining kidney, even when this is healthy, is always marked. Whether this is to be ascribed to direct reflex through the nerves of the sympathetic and cerebro-spinal systems, or to the sudden and burdensome physiological demands upon it, is unsettled. In most cases probably these two embarrassing factors are united.

One observed fact points strongly to the reflex inhibition as the more important—viz., where nephrectomy is performed on an organ long since useless by cystic disten-

tion, its ureter blocked by inflammatory adhesion around an imbedded calculus. Here the other kidney has for some time accustomed itself to the performance of double duty, yet here the same reflex shock may readily result in temporary, complete, or gradually increasing suppression.

I have not been able to find reference to any case like the one here reported, where renal disease simulating calculus was attended with alarming hæmorrhage, where nephrectomy was necessary to save life, and where a thorough patho-histological examination of the entire organ showed only a chronic pyelitis to be the cause of so serious a complication.

Consequently I would claim originality for this case in that heretofore, even if suspected, no such procatarctic cause for severe hæmaturia has been shown by operation and pathological examination. Hæmorrhagic pyelitis or chronic pyelitis with acute hæmorrhagic exacerbations would best designate the disease.

A SUGGESTION
CONCERNING THE INTIMATE RELATIONSHIP BETWEEN BULBO-NUCLEAR DISEASE AND CERTAIN OBSCURE NEUROTIC CONDITIONS OF THE UPPER AIR-PASSAGES.*

By JOHN NOLAND MACKENZIE, M. D.,
BALTIMORE.

The reciprocal relationship between lesions of the central nervous apparatus and certain morbid phenomena exhibited in the upper respiratory tract is a subject of surpassing interest, and one, strange to say, upon which comparatively little original work has been done. There has been too great a tendency for specialists to confine research within exact anatomical limits and within too contracted a sphere of observation.

The intimate connection between a large number of affections of the upper air-tract and the sympathetic and cerebro-spinal systems of nerves irresistibly obtrudes itself upon the recognition of even the most superficial observer, and it is therefore all the more remarkable that attention has not been sufficiently drawn in the direction of such an obvious fact. Except in the case of certain paralytic affections, whose pathology is often, but by no means always, sufficiently obvious, the subject is either passed by in silence by text-books on laryngology, or dismissed with a page or two of glittering medical generalities which amount simply to a confession of learned ignorance. Words take the place of explanation, and the more they multiply the more vague and indistinct the subject becomes.

There are a host of obscure neurotic phenomena seen in the upper air-tract that suggest themselves at once. Not to multiply examples, take, for instance, the disease known as "functional aphonia," or the affection to which Sir Morell Mackenzie has given the name of "spasm of the tensors of the vocal cords." What do we know concerning the pathology of either one of these affections? The conclusion is resistless that they are in some way connected with central trouble, and yet we know absolutely nothing of their primary causes. We know by empirical clinical experience that the former disease can be cured by the application of electricity within the larynx, or, for that matter, upon any indifferent part of the throat, and that the latter is in the vast majority of cases incurable. However we may delude ourselves and our patients into the belief that in the first case we accomplish a cure by direct stimulation of the laryngeal muscles, regard for absolute truth compels the confession that we do so by a sort of miracle, so to say, of psychic impression; while in the second case we do not cure, because we have no anatomical or pathological basis to go upon.

I have in numerous former publications, which are familiar to most of you and to which I need not therefore refer, endeavored to point out the intimate union between certain obscure respiratory troubles and disorders of the sympathetic nervous system, and have formulated a number of propositions which, I believe, may enable us to approach more nearly the scientific generalization of a host of phenomena whose kinship has never before been sufficiently considered.

While in some quarters I have encountered adverse criticism, and while open always to correction, my subsequent clinical experience encourages the belief that my former conclusions were in the main correct. But while the testimony of our special senses must accord to the sympathetic an important rôle in the pathology of many obscure affections of the upper air-tract, it must not be forgotten that it is often only one factor in the mechanism of the attack, while in other cases the cerebro-spinal system is the agent most conspicuously concerned. It is this part of the subject that I desire to speak of to-day.

I shall submit these remarks to you simply as a suggestion, and, in order to provoke discussion, will read some notes from a case which came long ago under my observation, not because they contain anything strikingly original, but solely to give those who may follow me in the discussion something tangible upon which to base their remarks:

Mrs. X., aged about forty, consulted me nine years ago with the following history:

She had enjoyed good health up to ten years prior to consultation, when her husband died a drunkard. Prior to and after his death she had had a great deal of domestic trouble. Examination of her family history and that of her husband reveals nothing positive. She has never had syphilis, nor received any injury in any part of the body. Her circumstances have always been good and habits temperate, and she is not naturally inclined to a nervous temperament. For some time prior to her husband's death domestic sorrow had led to much mental excitement.

Shortly after his death, while cleaning her room and apparently in perfect health, her face became suddenly drawn downward and outward to one side (the left). This was especially noticeable about the angle of the mouth. There was no difficulty in articulation and no other symptoms, and the attack passed off in three days under treatment. Following the attack there was an interval of apparent health up to within about a year before she consulted me. She had been washing clothes all day in the yard, and awoke the next morning to

* Read before the American Laryngological Association at its twelfth annual congress.

find that she had lost power in her right hand. Sensation in the fingers was abolished, so that she could not pick up things nor hold them in her hand. She could grasp the hand of her physician only with difficulty. With this was associated numbness and tingling in the extremities without loss of power, and twitching of one of the tendons in the palm. The tingling sensation extended into the throat and gave rise to considerable malaise. She ascribed this attack to having carried the wet clothes on her arm during the day before. These symptoms lasted about a week, and as they were disappearing she noticed slight difficulty in articulation, causing her to mumble her words. There was no aphasia. This grew worse, and she complained of some oppression in the chest. At the same time she noticed that her mouth was drawn a little to the left side. She took to bed, and in about a week began to improve. Her speech became clear, but she complained of pain in the throat and legs, the latter becoming swollen. All these symptoms disappeared, however, and several weeks after their subsidence, while sweeping her room, she was suddenly seized with a foaming at the mouth and puffing outward of the cheeks; had no other symptoms except tingling in the right hand. No fall, convulsion, etc. She walked up stairs immediately, but could only mumble out a few unintelligible words. When the violence of the attack had passed off she noticed a weakness of the tongue, with difficulty in its protrusion and difficulty also in articulation. At this time her legs were swollen, and she had tingling sensations in them with formication. The trouble with the tongue grew gradually worse, and about six weeks before seeing me first noticed slight dysphagia, especially in the deglutition of liquids. At the same time she was taken with pain in the back of the neck and shooting pains in the hand. These, together with occasional flushes of heat in the head, passed away. She remained in the above condition until two weeks prior to consultation, when she began to talk through her nose. She has lost flesh lately.

Symptoms on Admission.—Face has a characteristic lacrymose appearance, with a tinge of alarm. The mouth is lengthened and drawn closely across the teeth; its angles are depressed and the naso-labial sulci deepened. The tongue can be protruded, but with difficulty, and she can not lift it to the roof of the mouth, nor can she place it above the upper lip. Its movements are slow and evidently require effort to effect them. It is long, sharp, covered with a foul, white fur, but has no appearance of atrophy, nor are there any fibrillar movements. Its sensation is good and taste is unimpaired. There are small tumors at its tip (fibrillar?). The lips look normal (the patient thinks they are larger than usual). Can blow out a light at a foot from the mouth, but at a greater distance fails to do so. Can not whistle or kiss, but can close and open the mouth perfectly. Attempts at laughing result in a ludicrous expression of the face. The muscles of the mouth and pharynx react but feebly to the faradaic current. Sensibility is intact. There is no paresis or loss of sensibility in the other muscles of the face, head, and eyes. There is some difficulty in mastication, and the patient's laugh degenerates into a grimace.

There is complete paralysis of the soft palate and uvula, and the reflex excitability there and in the pharynx is notably diminished, so that these parts can be irritated without provoking anything but a feeble response. Sensibility and muscular irritability are not impaired. There is some congestion of the parts, but otherwise their appearance is normal. There is no deflection of the uvula.

Rhinoscopic examination of posterior nares and nasal pharynx negative.

The larynx is normal in appearance, but its reflex excitability is much diminished. This is especially noticeable on the epiglottis, whose surface can be irritated without provoking the slightest motion. There never has been the slightest trouble with vocalization, except slight fatigue on exertion. There is great difficulty in expiratory efforts, such as gargling, coughing, etc. She has a small amount of dyspnœa, which becomes considerable on exertion. The saliva is not increased in quantity, but is thick and tenacious from admixture with the buccal mucus, and has to be withdrawn from the mouth with the finger. The difficulty in expectoration is considerable. During sleep she is often awakened by a sense of suffocation, only relieved by withdrawal of the mucous secretion. During the daytime her handkerchief has to be constantly held to the mouth to catch the abundant secretion.

The patient speaks in a mumbling manner difficult to comprehend, and as though there was some difficulty in closing the glottis, although the excursions of the vocal cords are normal, as seen with the laryngoscope. No aphasia, no confusion of words or syllables.

The right hand and both legs show great muscular weakness. There is pain in the right leg and stiffness and tenderness about the neck.

Temperature normal; pulse regular, 120; respiration 30.

The patient's temperament since her attack has been nervous. Her friends say that without apparent cause she breaks out into spells of noisy weeping, followed by equally unaccountable laughter. Her intelligence is intact, appetite poor, bowels regular.

These observations and the history of the case were taken at her first and only visit, for, receiving an unfavorable prognosis, she never returned, and I am therefore unable to give any further particulars. The above-mentioned data are, however, abundantly sufficient to establish the bulbar-nuclear nature of the trouble. It is unnecessary to comment in detail on this case. It is one with which the neurologist more than the laryngologist has to do, but it is the representative of a class of cases from which both may derive instruction. If specialists in the different departments of medicine would, instead of standing aloof from each other, combine the special knowledge they possess in a common endeavor to elucidate the difficult problems which daily confront us, the hostile cry of ignorant criticism would be forever silenced by their discoveries for the common weal.

THE USE AND ABUSE OF THE GALVANO-CAUTERY IN THROAT PRACTICE.*

By HENRY SCHWEIG, M. D.

Since the accession of the galvano-cautery to the ranks of recognized therapeutic resources its use has become more and more restricted to a certain class of cases, and the indications for its employment have been from year to year more clearly and sharply defined. In no class of ailments, however, has this been more strongly exemplified than in the disorders occurring in the upper respiratory tract, so that to-day it may be safely assumed that, while there exist differences of opinion regarding the employment of the galvano-cautery in individual cases, still there can exist no two opinions in the matter of the general broad indications for its use. Many failures are recorded and negative results

* Read before the Section in Laryngology and Rhinology of the New York Academy of Medicine, May 27, 1890.

are not few, but careful analysis and investigation will not infrequently discover either improper selection of cases or a want of knowledge regarding the technique of galvano-caustic operations.

In throat practice the first class of cases in which the galvano-cautery promised brilliant results was vascular growths, and this was based mainly on the knowledge of the hæmostatic properties of the ferrum candens. While some observers reported brilliant results, others had only failures to chronicle, and with these conflicting data the perpetuation of certain operative procedures seemed anything but assured. The ablation of tumors, removal of papillomata, condylomata, tonsils, and mucous polypi, and amputation of the uvula were accomplished by the cautery.

Of cases that have come under observation during the past decade, those yielding particularly favorable results were, in first order, vascular growths and anterior nasal hypertrophies, and also slight deflections of the septum, hypertrophy of turbinated tissue, granular pharyngitis, hypertrophied tonsils, adenoid vegetations in the vault of the pharynx, and papillary enlargements at the base of the tongue. In the larynx the results have not been so encouraging. In anterior nasal and turbinated hypertrophies the most brilliant and lasting results can be obtained, and it is in just this class of cases where a want of knowledge of the technique of cautery work does much mischief.

It should be borne in mind that from the first moment of the closing of the circuit there is a steady increase of heat in the nasal cavity, and that scorching and interference with the integrity of the surrounding tissues becomes a source of menace, and that adequate protection of the contiguous structures should be secured. The apparent reaction so frequently noticed after cauterization with the galvano-cautery is in reality no reaction, but a scorching pure and simple, and inexcusable on account of its easy avoidance. Another cause for complaint in this class of cases has been the large areas of destruction remaining after the employment of the cautery, showing dry, glistening patches where the muciparous glands had been destroyed. Here is evidence of the unskillful use of a valuable therapeutic agent, as the method of subcutaneous destruction by the galvano-cautery, when properly practiced, leaves the lining membrane of the nose practically intact, and still completely destroys any redundant tissue that may exist. In the spur-like deflections of the septum much can be done to remedy the deformity without the pain and danger attending the use of the trephine, saw, drill, and chromic acid. No open surface remains to suppurate or serve as an avenue for the entrance of septic matter, very slight or no pain is felt during the operation if cocaine is employed, and very little after, there is no hæmorrhage, and the slough is thrown off in a comparatively short time.

But it is mainly in the pharynx—which, on account of its accessibility, is most frequently treated—that the abuse of the cautery is carried to its extreme. Permanent cicatricial contractions of the pillars of the fauces and ragged tonsils riddled with holes testify to this. I know of no other portion of the upper air-passages more sensitive to the action of the cautery than the faucial pillars, and I have often observed contractions following the free or incautious use of the cautery here which rendered deglutition and respiration painful.

That frequent complaint of singers and public speakers, granular pharyngitis, in which bunches of enlarged follicles have coalesced, forming elevated vascular ridges and interfering with proper voice production, is amenable to no other treatment that yields as good results as the galvano-cautery. We have here all the conditions that call for a destructive agent that can be easily handled, is free from danger when properly used, and the action of which can be limited to a nicety, destroying just enough of the hypertrophied tissue to leave a smooth and free surface.

Here as well, however, the destructive process may be carried too far and a condition far worse than the original one substituted if the potency of the agent employed is not borne in mind. It suffices simply to puncture each elevation. A double effect is thus secured, as, in addition to destruction of tissue, we also secure a slight amount of contraction in the cicatrices. Beneficial as this is, so harmful is it when carried too far, leaving, as it does, deep and annoying contractions.

Until a very recent date operations at the base of the tongue were attended with much hæmorrhage and pain, and interfered seriously with deglutition. At the present day, with the aid of the galvano-cautery and the irido-platinum wire snare, enlargements of the papillæ, for instance, can be reduced with ease, or can, if desired, be more slowly and perhaps more effectually removed by repeated punctures with the cautery point.

May I be permitted in this connection to again call attention to the subcutaneous method of destroying growths?* I have found it of great service in a number of cases of marked enlargement of the papillæ at the base of the tongue. In fact, it applies to all vascular growths, the destruction of which it is desired to secure without interfering with the integrity of the mucous or cutaneous surface and without leaving any appreciable breach of surface. Too much stress can not be laid on the advantages of this method of operating, as many dangers are avoided thereby and a clear field for operating is secured, as there is no hæmorrhage to interfere. For a fuller description, reference may be had to the article quoted above.

A word as to the form of battery to be employed. All batteries which depend for their action on the immersion of elements at the time of operation should be discarded, as, from the moment the elements come in contact with the exciting fluid, the strength of the current becomes gradually less and polarization begins. This objection does not obtain in the Grove system; but a more serious objection—the employment of two acids, and the necessity of almost daily refilling of the battery—makes this practically useless. The only form of battery which should be employed, and which can be relied upon to furnish a current of uniform strength at all times, is the storage battery, and this should

* Reflex Symptoms of Nasal Disease. By Dr. H. Schweig. *Med. Record*, Jan. 22, 1886.

in every case be provided with a German-silver wire rheostat.

It is impossible with the many forms of electrodes used in connection with a cautery battery to supply a current which, without certain modifications, will bring all electrodes to a uniform degree of heat, but with a properly constructed rheostat this can be regulated to a nicety. About ten years ago, when the storage system came into more general use, it occurred to me to establish a permanent cautery plant on my operating table, and this has so simplified the use of the cautery that I may be permitted to describe it.

In a closet convenient to the office a number of gravity cells are placed and connected by insulated wires with the storage cells, which are placed under the table. From the storage cells connections lead to two binding-posts fixed on the table, and between these two posts is placed a rubber button connected by means of a vertical rod with a rheostat directly under it, but concealed. By raising or lowering the rod—*i. e.*, by decreasing or increasing the resistance—any desired degree of incandescence can be obtained, and the heat of the lightest as well as the heaviest burner nicely regulated. The importance of this device becomes more apparent in the use of the wire snare, as, with the gradual diminution in the size of the loop, the current must be diminished. The same current which heats a loop of an inch to a red heat would bring a half-inch loop to a state of white heat, and destroy a still smaller one. The gravity cells remain permanently connected with the storage battery, which is being constantly charged and is always ready for use, and can be detached from its connections in the fraction of a minute if required for use elsewhere. The only attention which this plant requires is the addition every two or three weeks of a quantity of water to the gravity cells sufficient to compensate for loss by evaporation, and the occasional addition of sulphate of copper to prevent exhaustion of the cells. In this manner the use of the cautery is stripped of all its complications and becomes a matter easily controlled. A word of warning as to large electrodes and heavy, thick insulating material. In the nose and throat small electrodes only are required, as the more slowly we operate the greater the assurance that there will be no hæmorrhage; and in working in cavities—the nose, for instance—the room is so restricted that the working space is seriously diminished by a heavy insulator, and the field of operation is also obstructed.

In a word, in the use of the galvano-cautery the surgeon requires much fine discrimination and tact, and needs not alone a thorough knowledge of the technique of his work, but also a knowledge of the construction of the instrument employed by him, for without that he will not be in a position to meet the many little annoyances that may be caused by bad contact, improper connections, and breaks in the circuit. As a rule, the electrode should be heated to a cherry-red, and in nasal surgery the surrounding parts protected by a proper device. I find that the ordinary metal aural speculum answers every purpose.

The advantages of the cautery can be summarized in a few words.

Its employment is not followed by hæmorrhage, provided care is observed not to tear the electrode from tissues to which it may adhere, but allowing it to burn its way out, as it were.

It is a powerful hæmostatic.

Its advantage over other destructive agents lies in the fact that its action can be controlled and localized to a nicety, and does not extend, as in the case of the stronger acids, to contiguous structures.

There is no reaction and the process of repair is rapid.

There can be no doubt that many operators have discarded the cautery owing to bad or unsatisfactory results which might have been avoided by a closer study of the action of the agent employed by them, and it is my firm belief that those observers who have not yet employed the cautery will gain from its use results both satisfactory and convincing.

RECENT INVESTIGATIONS IN STRABISMUS.

By HARRY FRIEDENWALD, A. B., M. D.,

BALTIMORE,
LECTURER ON OPHTHALMOLOGY AND OTOLOGY,
COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE;
LATE ASSISTANT TO PROFESSOR HIRSCHBERG, BERLIN.

Since the appearance of Professor Schweigger's monograph on strabismus, ophthalmology has lost the peace of mind it had previously enjoyed in this respect. Its tranquil faith in the theories of its great masters was disturbed. Donders and Graefe and all the other leaders in the science had taught that a squinting eye gives up all its visual function in that part of the field which is common to both eyes, that its impressions were "excluded," and thus they explained the amblyopia generally found in such eyes (and therefore termed *amblyopia ex anopsia*) and the absence of diplopia.

But Schweigger found, or confidently believed he had found, that all this was false, and called it a "history of errors." From him we learn that the strabotic eye yields its full complement in the common visual act, and that the amblyopia mentioned above is congenital, in no way differing from ordinary congenital amblyopia, and, far from being the result of strabismus, is in itself a factor in its production. Abandoning the old theory of the "innate identity" of corresponding retinal areas, which had necessitated the "exclusion theory," he regarded the faculty of binocular vision as acquired, and, as such, as easily unlearned in early youth, and that in strabismus new associations take the place of earlier acquired relations. Thus he escapes the difficulty of explaining the absence of diplopia.

New facts bearing upon this discussion were few, and the matter has remained a disputed question. Light has, however, been thrown upon this subject recently. Dr. Hirschberger, of Munich, published an article entitled The Binocular Field of Vision of the Strabotic,* embodying the results of a long series of examinations and experiments made while assistant at the ophthalmological clinic of the Munich University. This article must be looked

* Binoculares Gesichtsfeld Schielender. Von Dr. Karl Hirschberger. *Münch. medicin. Wochenschr.*, 1890, No. 10.

upon as the most valuable and important contribution that has been offered in deciding this question.

Having seen him examine many of his patients, and having verified his results by frequently repeating his examinations for myself, I can testify to his results. The remarkable facts revealed, and their interest and many-sided importance, lead me to bring an account, as far as he has published it, before the American profession.

Recognizing that the mooted question could be solved in no other way than by accurately determining in strabismus the part played by each eye in vision, and not in certain parts of the field of vision only, but throughout the whole field, Hirschberger devised a method of examining as simple as it is efficient and ingenious.

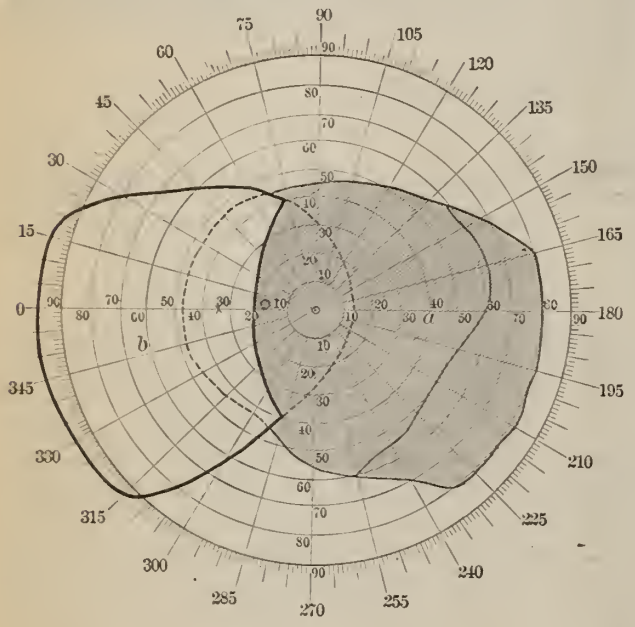

Fig. 1

He examined the field at the perimeter, leaving both eyes open, the non-deviating eye being directed upon the center; the test object used was a spot of blue color,* and a plate of glass of the complementary color—yellow—was held before one eye. To the eye seeing through the yellow glass the spot appeared black, and so it was easy to distinguish throughout the field where it appeared black and where blue, or, in other words, when it was seen by one eye and when by the other.

Subjecting cases of divergent strabismus of moderate degree to such an examination, he found a composite figure resulting similar to Fig. 1. This represents the field of a case of divergence of the left eye of 35°. The yellow glass was held before the right eye. The shaded portion shows where the blue spot was looked upon as black, the field of the right eye; the clear part where it was recognized as blue, the field of the left eye. This proves that *the field of the left squinting eye is somewhat restricted in binocular vision*, for, under normal circumstances, it should extend about 35° farther to the right, as is shown when examined singly; hence *there is exclusion in the squinting eye*. If, however, the experiment is reversed, the colored glass being placed before the squinting eye, we find that the form of the separate fields remains unchanged, the field of the normal right eye extending to about 20° on the nasal side, while in monocular vision it extends to 40° or 50°. This discloses a fact hitherto unknown—that in binocular vision the *non-deviating eye yields up a part of its field for the benefit of the squinting eye; that there is exclusion in the non-deviating eye!* This fact, as surprising and remarkable as it is, can be verified in most cases of strabismus.

The binocular field of vision in these cases consists of portions of the fields of each eye added to each other without overlapping or having parts in common, in this respect differing greatly from the binocular field of non-squinting eyes. There is a sharp line dividing the two portions.

To test the degree of the exclusion of visual perception, the reflex of a candle-light from a small plane mirror was used, and it was found that not even this intense light was seen in those parts which had been marked out previously as the areas of exclusion in each eye.

The size of the areas of exclusion was generally found to be in an inverse ratio to the degree of the angle of the divergent strabismus.

Examining the binocular fields in convergent squint in the same manner, they were found more or less as represented in Fig. 2. This is the field of a case of convergence

Fig. 2

of 30° of the left eye. The yellow glass was held before the right eye; *a*, *a* are entirely controlled by the right eye, *b*, *b* by the left; *c*, *c* are variable, in some cases belonging to the one, in others to the other eye, occasionally to both. As in the case of divergence, reversing the glass does not alter the form of the separate fields.

Though the figures in the cases of divergent and convergent squint appear very different at first glance, it is evident, firstly, that in both cases the macular region of the squinting eye has exclusive control of its part of the field of

* A blue spot was preferred, because the normal field of vision for this color is almost as large as for white.

vision, the non-squinting eye yielding up its function there entirely, and, secondly, that the most lateral part on the side of the squinting eye beyond the area of the normal field of the other eye is entirely allotted to the squinting one.

The regularity of these results was such that these statements may be looked upon as general laws. There are but few exceptions to the first. When the angle of strabismus is so small that the macular regions almost cover each other. *In this case the macula of the squinting eye yields up its function entirely.* The effect of this upon the vision of the squinting eye was very evident. In a number of cases of very slight divergent strabismus vision had been permanently lost in the temporal part of the retina, including the macular region (those parts where exclusion had taken place). That this was not congenital amblyopia but due to the exclusion was beautifully illustrated in a case of a young farmer whom Hirschberger examined twelve years after he had been operated upon for a high degree of divergent strabismus. At the time of the operation the boy, then aged nine, had one third normal vision, as the hospital record shows. Twelve years later the strabismus was exceedingly slight, but central vision had been lost and the patient could only count fingers eccentrically. In this case it was evident that the great failure of vision was due to exclusion.

In cases of strabismus of variable degree *complete exclusion* could not be found in any part of the field, and diplopia was easily called forth. The same is true of periodic strabismus or of strabismus that has not become fully established. These cases form other exceptions to the laws stated above.

The projection of the strabotic eye was examined and found in accordance with the strabotic position; in other words, objects seen entirely by the squinting eye are "projected" in their proper positions in space and not displaced as in cases of ocular paralysis. This projection is not congenital, but depends upon the position of the eye, as is shown by changes which it undergoes when the relative position of the eyes is altered by an operation which either relieves the strabismus entirely or diminishes it. In this false projection lies the explanation of the peculiar diplopia often found after strabismus operations—a diplopia equal to the angle between strabotic and the subsequent position.

This strabotic projection is lost in a few days, or may last for weeks or even months, the eye finally adapting itself to its new position. It was found that the whole retina does not undergo this change at one time, but that the peripheral parts adapt themselves much more rapidly, so that a careful examination will sometimes detect various forms of projection in different parts of the field of vision for the same eye, and, in consequence, different kinds of diplopia.

Conclusions.—The facts brought out by the article are:

1. *Exclusion* of certain parts of the field of vision is not only possible in strabismus, but *takes place in the non-deviating as well as in the squinting eye.*

2. *The binocular field of vision of the strabotic is made up of parts of the field of each eye, these parts rarely overlapping at any point.*

3. *That part of the field of the squinting eye which corresponds with the macular region of the non-squinting eye is always suppressed, and, vice versa, that part of the field of the non-deviating eye which covers the part upon which the macula of the squinting eye is directed is likewise suppressed. There is a sharp line of demarkation dividing the macular areas of the two parts of the binocular field.*

4. *When the degree of strabismus is very slight, the macula of the squinting eye suppresses its image for the benefit of the macula of the other eye.* This is the only case where the macula of the squinting eye does not take any share in vision, and is an exception to No. 3.

5. *The degree of amblyopia depends upon the part that the macula of the squinting eye plays in binocular vision*, this being the explanation of the enormous differences in the strabotic amblyopia.

6. *The squinting eye learns to project images properly.*

The corollaries to be drawn are numerous. I shall only call attention to the importance of early operations, especially when the strabismus is of slight degree, and of perfectly correcting cases of high degree, the dangers of slight degrees as far as central vision is concerned being much greater. The importance of training in binocular-vision subsequent to operating is likewise fully shown by these facts.

922 Madison Avenue.

OPERATIVE PROCEDURES IN THE BONE DISEASES OF CHILDHOOD.*

By V. P. GIBNEY, A. M., M. D.

It is with a certain degree of diffidence that I appear before the Surgical Society without a paper on Appendicitis or Suprapubic Cystotomy. The title I have chosen for some remarks this evening will suggest, I hope, to the members a rather important branch of the surgical art, and my object in calling your attention to this subject is to bring out a discussion on the management of the diseases and deformities incident to childhood. The most common form of disease in the class of subjects referred to is tubercular osteitis.

I am well aware that the general surgeon looks upon an orthopædic surgeon as a mechanician purely. If his appliances succeed in correcting deformity and curing disease, he is applauded. If the reverse occurs, we are spoken of in a patronizing way, and the lament is expressed that a surgeon was not consulted! While many operators speak and write quite sanguinely of their operative procedures in bone and joint diseases, there are a certain number, whose judgment is excellent and whose skill is unquestionable, who speak deprecatingly of such procedures. The writer of the present essay is convinced that the orthopædic surgeon should be familiar with operations on bones that enter into the formation of the joint. He is also convinced that the success of these operations depends largely upon the mechanical protection given to the limb or joint during the reparative process, and even long subsequent to the reparative process.

Our hospitals are so acute in their character that cases requiring a long course of treatment are seldom admitted.

* Read before the New York Surgical Society, May 14, 1890.

When such cases are admitted, the aim is to operate as quickly as possible, to get healing of wounds with as little delay as possible, and then order a discharge to make room for others. It is admitted at the outset that operations performed at the proper time and in the proper manner contribute largely not only to the relief, but the cure of tubercular bone lesions in children. It is urged, likewise, that proper mechanical means, whether in the shape of plastic apparatus or steel appliances, should supplement these operative procedures; and it is also stated as a matter of fact that the element of time still plays an important rôle in the successful management of these cases. The difficulties which still attend the complete eradication of tuberculous foci, even under the most favorable circumstances, make rapid cures of comparative infrequence. Not only one, but many operations are required in many cases to obtain the maximum amount of benefit.

Disease of the Vertebræ.—In Pott's disease of the spine, which is the most common form of disease affecting the column, we have, as you all know, an inflammatory process in the body of the vertebra. We are not sufficiently advanced as yet to locate definitely the special body in which the lesion occurs. We know that the process is seldom confined to a single vertebra. For this reason we hesitate to explore the body of a single vertebra, and it is considered good surgery to wait until we can more definitely fix upon the number involved. Notwithstanding that many cases have been reported wherein good results have been obtained, the general impression is that the cases so reported will not stand a close investigation when looking for end results.

The procedure which is most generally adopted now in affections of the column is what is known as laminectomy, which has for its object the removal of the thickened tissue surrounding the spinal cord. The operation is done, therefore, for compression myelitis. While I have had no personal experience in this operation, I feel that it is often justifiable, and that a certain proportion of cases can be cured. The surgeon who becomes expert in dealing with the lamina is sure to get a certain number of brilliant results. Of course, he must select his cases. A child who has been paraplegic for a long time, and has had what is regarded as the best mechanical treatment—one who has had rest in bed without benefit—may properly be regarded as a subject for this operation. My own way of managing a case of Pott's paraplegia or compression myelitis differs somewhat from the ordinary routine, and neurologists do not all agree with me as to the value of potassium iodide. My plan, then, is to apply a solid plaster-of-Paris jacket, with a head spring, and not rest satisfied until I have a perfect fit. I begin at once with moderately large doses of the potassium iodide, given in Vichy or milk, and increase rapidly up to fifty or sixty grains, three times a day; sometimes I go beyond this point. I keep the patient in a recumbent posture, or in a wheeled chair, with the limbs not too dependent, and avoid lifting or handling as much as possible. A perseverance in this course of treatment for six months ought to yield good results. If a good result does not follow in this length of time, I put the patient in bed, with weight and pulley at each end, and continue the potash. Where they are old enough, I employ the Paquelin cautery two or three times a week, light strokes, over the spinous processes. Every case, I think, should have the benefit of this treatment. It takes a long time, sometimes a year or a year and a half, but the child is comparatively comfortable; it grows fat, as a rule; can be wheeled out of doors, and many excellent results have been recorded. If all this fails, then I should have recourse to laminectomy. The parts can be easily reached, and a careful amount of dissection will enable one to remove the pachymeningeal thickening that produces the constriction of the cord. The necessity for fixation after an operation of this kind still exists, and the value of the operation can be greatly enhanced by proper mechanical support. Before undertaking an operation of this kind, however, it would be well to have a neurologist go over the muscles with the current, and find how much degeneration exists and what muscles are liable to benefit by having the compression removed from the cord.

Osteitis of the Hip.—The operations for disease at this joint are as follows: Partial arthrectomy, excision more or less complete, curetting of sinuses, division of muscles and tendons for the correction of deformity, osteotomy, and amputation. Cases come to the attention of the surgeon in the first, second, or third stages. It is my belief that if a suitable apparatus can be applied to a patient in the first stage of the disease and proper attention can be given this for a period varying from one to two years, a cure will result. By cure I mean resolution of the inflammatory process with restoration of the function of the joint. The responsibility in such a case is divided about equally between the parent and the surgeon. The parent can not be, or is not, convinced of the importance of following closely every direction given. The surgeon has so little faith in apparatus that his instructions are not clear and well defined. He manifests this lack of faith in various ways. The patient is keen enough to perceive it, and hence the instructions, although given with the tone of authority, are not followed. The reason why operative procedures are not employed in this stage of the disease is the uncertainty in the mind of the surgeon as to the nature of the disease. He either is or is not convinced that the lesion is tubercular. He is too prone to accept the statement of the parents that not a trace of anything hereditary exists in either member of the family. He pins his faith to some trivial fall, without even taking the trouble of a cross examination. Authorities even speak of simple cases and tubercular cases. I have been for a long time convinced of the importance of calling every case of hip disease in a child tubercular. I do this in spite of numerous opinions given by surgeons and physicians who discuss from a theoretical standpoint the nature of the bacillus. I do it because it forewarns me, and, being forewarned, I am forearmed. Without entering into any dissertation on splints, what are best and what are worthless, I prefer to say a word about the principles governing the management of a case in this early stage. The aim is to protect the joint against every trauma. In order to do this, some form of perineal crutch or axillary crutch must be employed. Trauma may

come in various ways. It may come from reflex spasm, from a blow or bruise, a fall or a strain. The trauma increases the hyperæmia about the focus of disease. It permits the inflammatory area to extend until the joint is involved more or less seriously. Knowing, as we do, pretty well the history of tuberculosis, we must not expect resolution to take place in a short time. The reparative process is exceedingly slow. If the patient does not do well on a portable splint, then he should be confined to bed with traction or with absolute immobilization. The value of trephining the trochanter and neck of the femur has not been fully impressed upon the profession, and hence its employment has not been general. Furthermore, the friends of the patient are slow to accept any operative procedures upon a joint which is not deformed. Much valuable time is therefore lost, and when the operation is done it is probably too late. I doubt very much whether it is worth while to waste time discussing this point.

Take, now, the case that comes to our notice in the second stage, or the stage of deformity, with or without abscess, it matters little. The number of surgeons who profess to effect a perfect cure in a case of this kind are very few. Unfortunately, some of those who do make this statement do not enjoy professional confidence. We have to admit, therefore, that complete restoration of function is practically out of the question. The aim, then, is to conduct the case to an issue with the minimum amount of deformity and with resolution of the inflammatory area. The adhesions which have taken place as a result will generally remain. More or less deformity will result, but a very good result can in many cases be secured with the proper use of apparatus. It is also difficult to prevent the increase of deformity in this stage, however great the co-operation at home. It is a comfort to know, however, that the little patient can be saved from pain, can lead an out-of-door life, and can get well with a trifling amount of inconvenience. It is in this stage that operations are of great value. If an abscess can be recognized in the gluteal region, coming apparently from the digital fossa, a good, clean excision can be made with happy results. Even a partial arthrectomy here yields good results. If the abscess, however, appears on the posterior aspect of the thigh, on the anterior aspect, or in the iliac fossa, an extensive operation, in my judgment, is not called for. If the operation is done, however, it should be made very thorough. My own observation on operations done under the conditions named is, that sufficient after-protection is not afforded. The wounds are very nearly healed, the fistulous track remains, the general health has improved considerably, the patient is put upon a pair of crutches or a "stock" splint from the instrument-maker, and discharged. The result is a recurrence of the deformity, an extension of the diseased area, and a very short limb.

Cases presenting in the third stage are the best for operations. By the third stage is meant not only deformity, but actual shortening of the limb, which shortening is due to change in the relationship which the neck sustains to the shaft, or a pathological dislocation. These are the cases of patients that usually enter hospitals; "*dernier ressort*" means excision or amputation. Generally the parts are riddled with sinuses, and it is next to impossible to completely remove all disease. From a pretty careful observation of such cases, it seems to me that the best plan is to postpone operations so long as the general health can be maintained, and so long as the patient is not suffering acutely. A good plan also is to curette sinuses, aim to reach the diseased foci one by one, eradicate by degrees, and finally, when the sinuses are all closed, do an osteotomy below the trochanter minor, a Gant operation, bring the limb down parallel with its fellow, get osseous union as soon as possible, protect the joint for some months afterward by a splint, then resort to a high shoe, and a good result is almost sure to follow. If amyloid degeneration threatens, it seems to me that amputation is preferable to an excision. It depends a great deal upon one's surgical judgment as to the propriety of an excision. If this operation fail, then an amputation can be employed.

Osteitis of the Knee.—The means we have at our disposal now for correcting a deformity at the knee enables us to conduct a case to a successful issue. If abscesses or sinuses exist, all surgeons, I think, are agreed that an excision is rarely called for. The operation of arthrectomy or partial arthrectomy with subsequent protection of the limb during a long period yields better final results than any excision. One reason that surgeons refrain from excision in young children is a knowledge of the growth of the bone at the epiphysis. They have long since learned that the bone is stunted in growth by removing the epiphysis. Another reason, which is not generally given, but which is of weight, is the tendency of the deformity to recur. A radical operation in the hands of a surgeon is thought to be all-sufficient. A month's or a few months' protection of the parts generally suffices. The case passes from under observation, and in the course of a year or several years the deformity has relapsed. This has occurred in a certain number that have come under my own observation. I have two cases now under treatment—one in the Out-patient Department and one in the hospital. The former is in a boy twelve or thirteen years of age, who had an excision done in one of the city hospitals when he was two years of age. The operation seemed to be thorough. He had the usual after-treatment, and seven years subsequently came under my notice at the hospital with a rectangular knee, both bones very much shortened, and his gait was most distressing. There was complete synostosis at the knee, and it was necessary to remove a large wedge-shaped piece of bone in order to correct the deformity. He is now wearing a posterior splint and an immense frame for a high shoe. The case in the hospital is that of a boy of five or six years, who has had several operations—one an excision and two partial arthrectomies—and his limb is not only greatly shortened, but bowed and much deformed.

There are several osteotomies for the correction of deformity about the knee, but these will suggest themselves to the surgeon, and individual judgment must be the guide. Osteotomy is usually for the correction of deformity.

The judicious use of plaster of Paris is a great help to us in such cases. The splint I employ after the deformity is corrected is that known as the Thomas splint, which means a perineal crutch.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co.

Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, AUGUST 16, 1890.

THE RELATION OF AMERICAN MEDICAL SOCIETIES TO SCIENTIFIC RESEARCH.

Of the several reasons that have interfered with the prosecution of original research by American physicians, aside from the fast disappearing obstacle of insufficient educational equipment, probably the most potent have been what some are pleased to term the essentially practical nature of the American, that causes him to look askance on any work not promising a pecuniary return; and a lack of money necessary to purchase apparatus, drugs, and the other paraphernalia requisite for any special research.

Many of our physicians have made valuable contribntions to medical science by investigations that have required considerable expenditure not only of time but of money as well. Undoubtedly there are some medical men in this country that wonld to-day be glad to work a solution of some physiological or pathological problem if supplied with the necessary appurtenances for such work.

At a few of our universities a limited nnmber of scholarships might be made use of by recent medical gradnates to pursue a course of special investigation; bnt what seems to be needed are means whereby a qualified man, in a village or town that has no university, can employ his leisnre and gratify his tastes and inclinations in conducting some scientific research. Some State medical societies offer a prize for the best essay on any professional subject that is the result of original investigation; and for several years a portion of the Boylston prize fund has been thus offered. But prizes are not the means by which the desired end may be attained.

The recent report of the Scientific Grants Committee of the British Medical Association has suggested the desirability of our State and national medical associations considering the adoption of a similar plan to theirs. During the past year that association has spent, in money advanced to physicians for the expenditures necessary in making special investigations, a sum equal to twenty-four hundred dollars. In different parts of Great Britain investigators have been studying various problems, snch as the inoculation of carcinoma and sarcoma on the lower animals from man; the vaso-motor functions of the cerebral cortex; animal heat, and also the invention of a suitable heat-measuring and heat-recording apparatus for accurately estimating the precise heat product of animals; an investigation of the constitution of certain pathological effusions; anthrax albumose; the coagulation of egg and serum albumin, vitellin, and serum globulin by heat; the proteids of nrine and albuminuria; whether the muscles of adduction and abduction of the vocal bands have cortical cerebral centers; the ptomaines in connection with typhoid fever; the localization of the heat-producing cerebral function; the action of morphine and a number of its derivatives: the influence of bile on pancreatic digestion; the comparative digestibility of different starches; and the chemico-physical character of certain proteids. Possibly none of these investigations wonld have received a prize if offered in competition to any society. And yet they are all of value in tending toward the ultimate solntion of varions problems; and they indicate the possibility of larger fields of usefulness for our numerous American societies than any that they have yet entered upon.

SURGEON PARKE AND THE MEDICAL PROFESSION.

Dr. Parke, whose brilliant services with the Emin Pasha Relief Expedition have excited the admiration of the civilized world, was on the 6th of June last presented by the editors of the *Lancet* with a massive silver salver, and on the evening of the same day was the guest of a brilliant representative gathering of the members of the medical profession, who had assembled to do him honor at a dinner at the Criterion Restaurant. Sir Andrew Clark presided. Mr. Jonathan Hutchison, Sir James Paget, Sir Prescott Hewitt, Sir Joseph Fayrer, Sir Spencer Wells, and many other distingnished members of the profession were present. After several speeches suitable to snch an occasion had been made, Surgeon Parke, amid great applause, rose to respond and made a very modest speech, in the course of which he said that he would remind the company, if they were not already tired of hearing abont Africa, that it was just three years and three months before that Mr. Stanley started from England to bring relief to Emin Pasha—not to bring him away from Africa, but to bring him relief. With a force of about eight hundred strong, they started from the mouth of the Congo on March 18, 1887. The shortest time any of them spent in the forest was one hundred and sixty-two days. The pygmies or dwarfs they met stood about three or four feet high, had tiny hands and feet, with fairly good features, and were bright and intelligent. They were covered all over with down, such as is seen on the cheeks of a boy of eighteen or nineteen in this country. The European provisions that the party took with them were finished within a month. The two bottles of brandy which each had were also soon exhausted. They had exactly the same food as the natives—bananas, with occasionally a goat a week divided among six or eight.

The Enropeans survived much better than the natives did. Of the two Europeans who died, one died from climatic causes and the other was murdered. Emin Pasha was qualified in medicine by a German degree, of which he was very proud. He spoke twenty-two languages, of which he could write and read thirteen. When they started he (Surgeon Parke) took the precaution of vaccinating the majority of the men, and when the epidemic of small-pox broke out only four were attacked by the disease, and none of them died. On the other hand, the camp-followers, who had not been vaccinated, took the disease in a bad form and died in great numbers. After a three years'

march across Africa they reached Zanzibar with Emin Pasha. He wished to place on record the great admiration he and his brother officers felt for their illustrious leader, Mr. Stanley.

MINOR PARAGRAPHS.

RECURRING MULTIPLE OSTEITIS AMONG PEARL WORKERS.

In a recent number of the *Centralblatt für Chirurgie* there is an article by Dr. Levy on the hitherto little-known disease which attacks workers in pearl. The first formal observations upon the phases of the affection were made in Vienna, when some twenty-five cases were reported. The author has seen five cases during the past four years in Berlin. These had occurred among the younger workers. After from four to six years of such employment a form of osteitis would appear involving principally the maxillary bones. The symptoms were found to subside with a change of occupation, but would reappear in some other locality upon resumption of the pearl work. In one of the cases the patient had suffered recurring inflammation of the scapulæ, and in another the lower half of the femur had become involved, exclusive of the epiphysis. Dr. Levy is of the opinion that the affection is caused by the pearl-shell dust which fills the air during the grinding process and insinuates itself into the patient's system. Just how it operates then is an open question pending further elucidation.

LOCAL TUBERCULAR INFECTION.

In a recent number of the *British Medical Journal* report is made of an accident which befell Dr. Gutzman, of Berlin, and which may serve as a warning to surgeons and pathologists to be careful in the handling of tuberculous tissues. On February 19th, while Dr. Gutzman was holding an autopsy in the case of a patient who had died of acute miliary tuberculosis, the nail of his right middle finger was slightly raised from the matrix. A pricking sensation was experienced at the tip of the finger, but no wound could be seen. The hand was thoroughly disinfected in a sublimate solution and alcohol, and the incident forgotten. On March 20th the end of the finger became painful, a small abscess being found under the nail. This was opened, and the pus removed, on being examined by Ehrlich's method, was found to contain three tubercle bacilli. The cavity was cleaned out and disinfected with alcohol. So far there has been no lymphangeitis or glandular involvement and no rise of temperature. Dr. Gutzman regards the case as an example of local tubercular infection.

PROFESSIONAL AND COMMERCIAL CONFIDENCE.

The August number of the *Virginia Medical Monthly* asks if we will not retract our statement in regard to a certain New York commercial house, that it "still deserves and receives the confidence of the medical profession." This is a journal of medicine, not one of finance, and financial transactions are not proper subjects for its comments, unless they involve medical points, and we should not have alluded to our contemporary's article on the house in question but for the reason that it cited a letter published by us from which it seemed to draw conclusions that we did not and do not look upon as warrantable. The *Monthly* now makes its own accusation against the firm, apparently relating to business matters. With such matters, as we have said before, we have nothing to do, and we have no reference to them when we speak of a house as deserving and receiving the confidence of the medical profession, but to the character of its dealings with the profession, and that fact our readers doubtless understood; hence we have no retraction to make.

SUBBENZOATE OF BISMUTH IN THE TREATMENT OF SOFT CHANCRE.

A recent issue of the *Medicinisch-chirurgisches Central-Blatt* contains an article by Dr. E. Finger, of Vienna, in which are given the results of his therapeutic endeavors with subbenzoate of bismuth as a topical application in the treatment of soft chancre. The compound is described as being made by heating nitrate of bismuth with potassium nitrate and sodium benzoate. The precipitate, subbenzoate of bismuth, is collected on a filter, washed with water and alcohol, and dried. The author reports its use in sixteen cases. Some stinging sensations follow its application, but these are not severe. Six or eight applications were sufficient to secure a healthy surface, the dressing being made twice in twenty-four hours. Dr. Finger seems to consider the subbenzoate a valuable substitute for iodoform and the more violent cauterizing drugs where they are contraindicated.

MICROBES IN HAILSTONES.

Truly in the midst of life we are in death. A recent number of the *British Medical Journal* states that Dr. Fontin, a Russian observer, has demonstrated the existence of pernicious microbes, of terrestrial origin, in hailstones. He has found that the water produced by the melting of the hailstones used in the experiments yielded an average of 729 bacteria to the cubic centimetre. The fungi of yeast and mold were absent, but nine different bacteria were discovered, including the *Bacillus mycoides*. As the abiding place of this bacillus is the earth, the fact that it and its pestilential congeners can be carried to the heavens and returned here with hail, rain, and snow, and directly convey infection, is another of the discoveries which, while adding perchance to the glory of science, show the blissfulness of ignorance.

PRESERVALINE.

In the bright lexicon of commerce this is the name of one of a number of preparations sold to milk-dealers to enable them, by adding it to their milk, to palm off stale milk on the community. It is supposed to consist mainly of boric or of salicylic acid. Ten per cent. of the milk furnished by dealers supplying Brooklyn is said to have had one of these substances added to it. The persons concerned profess that the milk is not made injurious by this procedure, but it is very obvious that it may become injurious under certain circumstances, and the State Dairy Commission is quite right in declining to leave that question to the milkmen's discretion. Certainly the community has a right to be protected from surreptitious drugging.

HÆMATURIA AND GARDEN RHUBARB.

Several correspondents of the *Lancet* have recently reported some unusual urinary troubles consequent upon eating ordinary rhubarb, or pie-plant as it is occasionally called. The symptoms are frequency of micturition, hæmaturia, dysuria, and lumbar pains. This effect of the rhubarb seems dependent upon the use of hard water for drinking purposes, the oxalic acid of the rhubarb combining with the calcium in the water and forming numerous small crystals of oxalate of calcium that—it is suggested—lacerate the uriniferous tubules in passing through them. Similar consequences have been noted after eating gooseberries and acid apples; and an explanation of obscure urinary troubles in localities where hard water is used is thus afforded.

THE TOXICITY OF BILIRUBIN.

Dr. G. de Bruin, in an Amsterdam thesis, arrives at the following conclusions regarding bilirubin: That, as Bouchard affirms, not only is it a poison to the organism, but, moreover, it has properties more toxic than the other biliary constituents, and is a more intense poison to the heart of the frog and probably also to the mammalian heart; that it occasions disorders in the parenchyma of the kidneys: and that it is probably a poison to the central nervous system.

THE TREATMENT OF INCIPIENT INSANITY.

In a June number of the *Lancet* commendatory reference is made to the steps taken by the West Riding County Council in its effort to check, if possible, the increase of insanity in that county. The approved arrangement at the West Riding Asylum affords an opportunity for free medical consultation to those suffering from mental or nervous diseases, especially in the early stages. The attempt thus to treat insanity in its incipiency has been so far successful that it has been decided to extend the system to other asylums. This subject has of late received serious attention at the hands of the New York Neurological Society, the aim being an early adoption of some plan which will afford opportunity for the study and treatment of insanity in its earlier forms.

ANTIPYRINE IN ERYSIPELAS.

Dr. Favre, of Fribourg, says the *British Medical Journal*, has reported an unusually severe case of erysipelas showing the high curative value of antipyrine. A woman, aged thirty years, suffered from facial erysipelas accompanied by somnolence, vomiting, constipation, and high fever. In spite of applications of cold, carbolic acid, ichthyol, corrosive sublimate, strips of adhesive plaster, etc., the morbid process gradually extended over the scalp, neck, chest, upper extremities, abdomen, and buttocks. On the tenth day the administration of antipyrine was begun, with the result that the febrile symptoms were at once decidedly reduced, the eruption soon ceased to spread, and the patient's subjective state was greatly improved.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 5, 1890:

DISEASES.	Week ending Aug. 5.		Week ending Aug. 12	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	35	7	40	5
Scarlet fever	49	6	28	2
Cerebro-spinal meningitis	6	5	3	2
Measles	171	13	109	8
Diphtheria	69	22	36	11
Varicella	0	0	1	0

Westphal's Successor.—It has been announced repeatedly from Berlin that Dr. Grashey, of Munich, would succeed Professor Westphal. For some reason this appointment has not been consummated, for we are now informed, through the *Lancet*, that Dr. Friedrich Jolly, professor of mental therapeutics at Strassburg since 1873, has been chosen for the place. Dr. Jolly is about forty-six years of age, and has a reputation for original research in his department and for literary ability.

Dr. William Nelson Blakeman, of New York, died on Sunday, the 10th inst., in the eighty-sixth year of his age. The deceased was a native of Connecticut and a graduate of the Yale Medical College. From the time of his graduation, in 1832, until within three or four years of his death he was engaged in general practice in New York.

The Honorary Degree of LL. D. has been conferred by Dartmouth College on Dr. Edward Cowles, the superintendent of the McLean Asylum in Massachusetts.

Change of Address.—Dr. William A. Valentine's new number is 45 West Thirty-fifth Street.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 9, 1890:*

Wales, P. S., Medical Director. Ordered in charge of the Museum of Hygiene, Washington, D. C.

Bright, George A., Surgeon. Ordered to the U. S. Steamer Constellation.

Mackie, B. S., Surgeon. Detached from the U. S. Steamer Constellation and ordered to Naval Hospital, Philadelphia, for medical treatment.

Derr, E. Z., Surgeon. Ordered to the U. S. Steamer Minnesota.

Waggener, J. R., Surgeon. Detached from the U. S. Steamer Minnesota and ordered to the U. S. Steamer Kearsarge.

Moore, A. M., Surgeon. Detached from the U. S. Steamer Kearsarge and granted three months' sick leave.

Letters to the Editor.

THE SUPRA-ORBITAL PRESSURE TEST OF MALINGERING.

U. S. S. Pensacola, *August 1, 1890.*

To the Editor of the New York Medical Journal:

Sir: It may be of interest to the readers of the article by Dr. J. T. Eskridge, published in this Journal of July 26th, to know that supra-orbital pressure in cases of true epilepsy has no effect. Supra-orbital pressure has been practiced frequently by me while house surgeon to the Chambers Street Hospital, New York, in cases of malingering, hysteria, alcoholic coma, and delirium tremens, with remarkable success. I published in the *Record* for August 27, 1887, an article on this subject, and agree with Dr. Eskridge's account of his successes. Could you refer me to the observation of "a German physician" upon this same point? He was mentioned in Dr. Eskridge's article.

Lute L. von Wedekind, M. D.,
Assistant Surgeon, U. S. Navy.

ARSENITE OF COPPER IN DIARRHŒA.

240 West Thirty-fourth Street, New York, *August 4, 1890.*

To the Editor of the New York Medical Journal:

Sir: I wish to call the attention of your readers to the value of arsenite of copper in the treatment of diarrhœa, dysentery, cholera morbus, and cholera infantum. I have not lost a single patient with cholera infantum since I began to use it. It is given largely diluted with water, and is not at all disagreeable to take. I think it was Dr. John Aulde, of Philadelphia, who first advocated its use, about two years ago. I have used it about thirty times within a few weeks without a single failure. It is put up in tablets of $\frac{1}{100}$ of a grain, one of which is to be dissolved in four ounces of water, and a teaspoonful of the solution (containing $\frac{1}{3000}$ of a grain) taken every fifteen minutes for the first hour and then every hour until relief is obtained. For children proportionally smaller doses are used. I feel sure that arsenite of copper may be made to reduce the mortality by cholera infantum as bichloride of mercury has reduced that by diphtheria.

Branch Clark, M. D.

Proceedings of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twelfth Annual Congress, held at Baltimore, on Thursday, Friday, and Saturday, May 29, 30, and 31, 1890.

The President, Dr. JOHN N. MACKENZIE, of Baltimore, in the Chair.

The Relationship between Bulbo-nuclear Disease and Obscure Neurotic Conditions of the Upper Air-passages.—The PRESIDENT read a paper on this subject. (See page 176.)

Dr. F. H. BOSWORTH was invited by the Chair to open the discussion. He said: I regard the case as very interesting, but I can not agree with the author that its bulbo-nuclear nature has been clearly established. It seems, on the contrary, that the evidence presented would establish the diagnosis as neuritis and not bulbar disease.

The PRESIDENT: Of what nerve?

Dr. BOSWORTH: Of the trifacial particularly. This, however, is merely a suggestion. If it is bulbar disease, we should decide what form. Is it a clot? or a thrombus? Is it softening? or a tumor? Bulbar disease is not enough; we should be able to state its nature as well as its place. To my mind the case is not of this kind, but may be a neuritis.

Dr. D. B. DELAVAN: This subject in general is perhaps the most interesting one in the laryngology of to-day, and is certainly the newest and least understood. The fact that eminent diagnosticians disagree, and that they advance ingenious theories of pathology only to have them overthrown by post-mortem investigation, shows that we are only on the threshold of the matter. Ever since Gottstein, following the example of Hughlings Jackson, called attention to the frequency with which laryngeal paralyses of central origin were due to bulbar lesion, there has been observed a tendency to refer all cases with similar symptoms to bulbar disease.

Garel has lately reported two cases in which the laryngeal paralysis was produced, not by bulbar disease, but by a cortical lesion. While it has been fully established that many cases are due to bulbar lesion, it is also possible that the same symptoms may depend upon a central disease of other than bulbar origin.

While it may not be possible to distinguish these cases now, future observation will enable us to determine more accurately the diagnosis between them. A paper, by a well known pathologist, upon the laryngological relations of tabes, or locomotor ataxia, is soon to appear, in which that subject is very thoroughly and philosophically considered, the writer especially dwelling upon the subject of laryngeal crises in tabes. The conjoined study of such cases by laryngologists, neurologists, and pathologists is particularly desirable.

Dr. BOSWORTH: I fail to recall any well-authenticated case of laryngeal paralysis in which the symptoms were due to cortical lesion; any case of central disease where it was shown post mortem that the cause of the paralysis was not in the bulb and was in the brain. In the noted case referred to by Dr. Delavan, the reporter has had reasons submitted to him for making a change in his diagnosis since that case was published. Gottstein's cases attracted attention to this subject, but he did not go much further than Hughlings Jackson, who, from a series of clinical observations, concluded that the source of the paralysis of the laryngeal muscles was in the medulla.

Dr. DELAVAN: In reply to the last remark, physiological experiments upon monkeys, dogs, and cats have clearly shown that a cortical center for the larynx does exist in them; if it is present in the lower animals, as has been conclusively proved, it is proper to assume, by analogy, that such a center also exists in man. Even if it has not yet been fully demonstrated by post-mortem examination, this failure may be owing to faulty methods and imperfect investigation. The center undoubtedly exists. There are cases in which laryngeal paralysis has occurred, and in which no bulbar lesion was found after careful search, where the lesion was evidently in the brain. In the cases I have reported the existence of a bulbar lesion was demonstrated; there are other cases on record where there was no such lesion found, but where, on the other hand, there was distinct lesion of the cortex.

Dr. BOSWORTH: Psychical centers for the larynx in the cortex I am willing to admit, but not motor.

The PRESIDENT inquired what experiments were referred to as those upon which Jackson's views were based.

Dr. BOSWORTH: Jackson's views were not based upon experiments, but upon cases. Some years ago, in a paper upon this subject, the speaker discussed this question, and the whole subject was gone over. There are practically but two forms of laryngeal paralysis—abductor paralysis and recurrent laryngeal paralysis.

The PRESIDENT: In closing the discussion, I have only one thing to say. Dr. Bosworth seems to doubt the diagnosis of bulbar disease in the case, and believes it to be one of neuritis of the trifacial nerve. How trifacial neuritis could produce the symptoms recorded I am at a loss to know. Unless the trifacial was distributed to the throat and back of the neck, the œsophagus, tongue, and other organs, the dorsal region and lower extremities, as well as to the face, loss of its function could not produce the phenomena present in the patient. The symptoms as recorded correspond closely with those presented by others as symptomatic of bulbar disease, and I can only conclude that he must have failed to hear the notes of the case as I read them.

(*To be continued.*)

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION IN MEDICINE.

Meeting of April 11, 1890.

The President, Dr. ATTHILL, in the Chair.

Massage.—Dr. KENDAL FRANKS read a paper on this subject. He began by a historical sketch to show that this method of treatment was not a novel one, that it dated back to the earliest times, and was used among all the nations of the world. It fell into disrepute among physicians and surgeons, because it was allowed to fall into the hands of charlatans and quacks; but that in recent times it had been revived, and had been taken up and practiced by leaders in the profession in every country, and, owing chiefly to anatomical and physiological advances, massage had secured a position in therapeutics from which it could not well be removed. He then explained its physiological *modus operandi*, and showed that the effects it produced could scarcely be brought about by other means. He quoted cases to show its power in neurasthenia, and quoted one case to show that even when massage was followed immediately by a fall in the temperature of the body, this was not always a contra-indication to its use. Another illustration showed how its effects were interfered with by unsanitary conditions, but that a good result immediately followed a change of lodgings. General neuralgic pains, accompanied by sciatica on one side, with a history of fourteen years, was cured by, firstly, nerve-stretching of the sciatic, and, secondly, by general massage. An aggravated case of insomnia, with great depression, existing on and off for years, yielded completely to a course of this treatment. The

use of massage in certain paralytic affections was dealt with, and the cases in which it was likely to succeed were indicated. These were illustrated by the history of a case of infantile paralysis, and by a case of complete paraplegia of both legs from the hips down, which followed a severe attack of malarial typhoid fever contracted in Cyprus. The treatment, which extended over the best part of a year, was followed by complete cure. The speaker advocated a modified system of massage in cases of gout, by which he had found that a fresh attack of the disease was long delayed, and immediate relief was speedily attained. In surgical cases local massage was frequently useful, and produced astonishing results in recent sprains and fractures. In a case of Pott's fracture, massage was employed eighteen days after the accident, and the patient was enabled to walk with ease, with a freely movable and painless joint twenty-two days later. A boy, aged fifteen (who was exhibited at the meeting), with a transverse fracture of both bones of the leg, was able to raise the leg from the bed without assistance on the twentieth day, and was able to walk about with a light support on the leg on the twenty-sixth day.

Dr. Cox believed, from what he had read of the experience of Weir Mitchell and Playfair, that the importance of massage, carried out in detail, combined with high feeding, rest, and isolation, could not be exaggerated; but, of course, bodily exercise achieved better results than massage in stimulating respiration and the circulation of the blood.

Dr. Ormsby said he had had considerable experience with massage since 1880, and he was fully sensible of the utility of that method of treatment in suitable cases; for instance, in the case of a young lady, who for nearly three years occupied a recumbent position suffering from hystero-paralysis, he had adopted massage as part of the Weir-Mitchell treatment, and it had proved highly beneficial, after almost every other form of treatment had failed; but there were many cases in which hysterical young ladies, when the treatment was abandoned, relapsed. Massage of itself would not suffice. He had more faith in Weir-Mitchell's treatment, which combined massage with seclusion, rest, electricity, and dietetics. While regarding massage as a valuable agent in suitable cases, he was satisfied that it was not a cure-all, and that from its indiscriminate use it was desirable the treatment should be placed on a scientific basis. He held that massage in surgery for recent fractures was wholly out of place, and he could not understand how any surgeon of experience would adopt it in a compound fracture or a Pott's fracture. In the case of the valet referred to it might have been that there was no fracture at all. It was not uncommon to find instances of resident pupils putting up accidents as fractures which, on examination by the visiting surgeon, proved not to be fractures.

Dr. Tobin mentioned that in the northern parts of India he had seen massage adopted to put horses into marketable condition with the minimum expenditure of material. Balls composed largely of ghee and sugar were shoved into the horse's throat, and some hours afterward the animal was massaged at the particular parts where development was desired. The masseur with gloved hands pounded the flesh at those parts; but the horse was never exercised, and so the required development was brought about in the cheapest way. Although the horses were bought in large numbers for the artillery, he did not consider the animals were in condition to "go," their lungs and heart not being in a corresponding state of development. Hence he thought it was advisable to combine exercise with massage. Indeed, remembering how old the practice of massage was, it seemed anomalous that medical men should have abandoned it for their patients, while they kept it in force for their horses, which always throve when well groomed.

Dr. Wallace Beatty said he had had experience of a remarkable instance in 1884 of the benefit of massage. An army medical man who had been in India had got intermittent fever and had lost the power of digestion, so that he had been unable to take anything but milk, and that in small quantity. Any other food had produced heartburn and made him miserable. A Dublin physician, who had treated him for two or three months without doing any good, was of opinion that he had malignant disease of the stomach. At length the patient had come to him, and he had seen him along with Dr. Head. Various things had been fruitlessly tried. The patient was losing flesh—from ten stone he had gone down to seven, and his tongue had been constantly furred. As a last resource, he had proposed to try massage; and the patient, having consented, had been placed in the Adelaide Hospital, where his brother, who was a strong man, was also accommodated in order to massage him. In nine days his tongue had got clean, he had gained a stone in weight, and from that out his progress to recovery had gone on till he was able to resume duty in Dublin.

Dr. M. A. Boyd said he had had some five or six cases treated by massage, and two of these with such success as to make a great impression upon him. One was that of a lady, aged fifty, who had had sciatica of two years' standing, for which she had been blistered, fired, and punctured, and received hypodermic injections of morphine, and even electricity, without avail. At last he had tried massage, and in three weeks the pain had disappeared. The lady had remained well for two months, when she had got sciatica in the opposite side. After three weeks' treatment by massage the pain had disappeared altogether. The other case was one of alcoholic neuritis, which, having resisted treatment by electricity, had been ultimately cured by massage. Dr. Franks had omitted to notice that very important group of paralytic cases—namely, paralysis depending on neuritis.

Dr. Alfred Smith said he had found massage beneficial in cases of prolapse of the uterus, and of accumulations of the pelvis, the products of cellulitis, as he had already detailed in a communication which he had read before the Obstetrical Section.

Dr. Heuston observed that he had employed massage with signal success in a case of traumatic paraplegia. A soldier in the Egyptian campaign had been occupied at earthworks which had fallen in, burying him in the *débris*. When dug out he had been found to be insensible, and upon being restored he had had paraplegia. He had been sent to the base hospital at Cairo, and thence he had been invalided home to Netley, where he had been kept for a year, till he could move about on crutches. Having been discharged, he had gone home, and after a couple of years he had been able to go about with the aid of sticks. Then he had suffered from his bowels and suppression of urine. Having taken him into the Adelaide Hospital, under massage treatment he had recovered, and had been able to walk about in two months, when he had been discharged cured.

Dr. Ninian Falkiner suggested the utility of massage in amenorrhœa to bring on the menstrual flow.

Dr. Franks replied. Massage would be found beneficial in infantile paralysis, owing to the great developmental power in the child, while it was not so likely to succeed in arresting progressive atrophy in the adult. Dr. Ormsby's strictures on the use of massage in fractures were founded on theory only. There was no error in diagnosticating the fracture, and he was satisfied that the results described had been achieved by massage, which he believed would be the great treatment of the future for fractures. He did not refer to compound fractures, in which he would hesitate to employ massage; nor could he speak positively of the treatment in certain oblique fractures, or

fractures about the neck of the thigh bone. But what he claimed for massage was that it induced rapidity of union without deformity by preventing adhesions from forming around joints. As regarded the interesting cases referred to by Dr. Smith, he had himself advised massage in a case of retroflexed uterus, for which a pessary was used. The pessary was removed, and, massage having been tried, the uterus became normal, and there was no need to put in a pessary again.

SECTION IN STATE MEDICINE.

Meeting of April 25, 1890.

The President, Dr. Foot, in the Chair.

The Infectious Diseases (Notification) Act, 1889.—Dr. Cosgrave read a paper on this subject and its extension to Dublin. Breach of confidence might apply to voluntary notification, but once notification was required by the Legislature, there was no breach of confidence, but the notification was put on the same footing with a certificate of cause of death or of successful vaccination. Dr. Cameron, of Leeds, had shown that voluntary notification had only dealt with from one case in five to one case in three, and then often after the power of doing good was gone. The small fee was objectionable from a medical man's point of view, but a guinea fee would be decidedly objectionable to the rate-payers. The act came into force in Dublin on March 1st, but had not yet been acted upon. When it was, its success would depend upon the skill and tact of the sanitary officials and upon the hearty co-operation of the medical men. The sanitary officials ought to be skilled and to be required to pass an examination under some independent body before being appointed. The act was already in force among three fourths of the population of Great Britain, and the medical officers of health had generally reported in its favor.

The President said it was one thing for the Legislature to lay down a scheme for discovering the causes of disease, tracking its sources and stamping it out, but it was another to carry out that scheme successfully; and, in his opinion, the workability of compulsory notification would depend on the general practitioners. He missed from the act the salutary provision of insisting on having observation wards for the reception of cases of doubtful diagnosis, such as were at present attached to some of the general hospitals. It would, he thought, be actionable if a person erroneously notified as suffering from diphtheria or scarlatina were bundled off to a hospital for infectious diseases and there got one of those infectious diseases.

Dr. William Moore was glad to learn from Dr. Cosgrave's personal experience that compulsory notification was not in the slightest degree irksome. He regarded the system as being of enormous advantage. The probability of the advantage of the system in epidemics of small-pox or scarlatina was indicated by the fact that in one outbreak forty cases were traceable to the existence of scarlatina in a milkman's shop. He deprecated the shabby treatment of the profession by the Legislature in awarding the miserable pittances of 2*s*. 6*d*. and 1*s*. as fees.

Dr. Grimshaw, Registrar-General, said that the principal difficulty turned on the question of removal to hospital of the cases notified without risk. There must always be the difficulty of mistaken diagnosis; and hence it was incumbent on the health authorities of the city to see that proper observation wards were provided for the reception of doubtful cases. Indeed, he considered it would be little short of criminal neglect if such wards were not provided. The idea that people could not get two infections diseases at the same time was dead and buried long ago; and, therefore, he thought the leaders of the medical profession should press upon the authorities the necessity of making provision for the difficulties of mistaken diagnosis. He did not think there was any grievance in having to notify infectious diseases. As to the physician disclosing the patient's confidence, once compulsory notification became the law of the land, the question of confidence was at an end. Every medical officer of health whom he had spoken to testified to the diminution of disease as the result of notification.

Dr. R. Montgomery thought that the opinion of the Section, as indicated in the remarks of the Registrar-General, should be communicated to the Dublin Corporation and the Board of Guardians, so that observation wards might be provided for doubtful cases.

Dr. Doyle was of opinion that the interests of general practitioners would suffer under the act unless they were enabled to follow their cases into hospital. Even at present there were many cases of persons well able to pay who, by going into hospital for operations, were lost to the general practitioners. While he was not an opponent of compulsory notification, he would devise some means of avoiding the injustice of depriving general practitioners of their pay cases.

Dr. Cosgrave, in reply, said the public health authorities were bound to provide proper accommodation where it did not exist. In Cork Street Hospital observation wards were worked with great care to prevent the mixing of different infections diseases. It was the fever wards in general hospitals that were so dangerous. He considered the smallness of the fee fixed by the act a necessity, and suggested that those who did not care to take it might let it go to the Medical Benevolent Fund.

The State Medicine Qualification.—Dr. Grimshaw read a paper on this subject.

The President was of opinion that there ought to be two qualifications, a higher and a lower, in state medicine—a lower grade for the common-sense practical man, with a good nose, and knowing something of the rough diagnosis of infectious disease, and the higher for those who would be called on to advise in the weighty matters of social science.

Dr. William Moore held that the humblest in the community were entitled to the best advice; and he thought that the majority of the examining bodies had accepted the suggestions of the General Medical Council.

The Boarding-out System for the Insane.—Dr. Conolly Norman read a paper on the boarding out of pauper lunatics. While asylums were a matter of necessity for a large number of the insane, they could never be made homes. Therefore such lunatics as could live outside asylums would be happier and better, if under suitable supervision, than those who were incarcerated in public institutions for life. Economic and other considerations were of less consequence than the advantage that might accrue to the insane under favoring circumstances and under a well-worked system of boarding out. The speaker briefly considered the working of the Gheel system and the Scotch boarding out. He very strongly condemned certain features in Gheel—the boarding out of dirty and semi-dirty patients, the boarding out of patients in estaminets, the use of restraint, and the too great liberty accorded to some better-class patients. The Scotch system afforded a better model. He laid down the conditions necessary to render patients suitable for boarding, and the restrictions and safeguards under which such a system must be worked. He differed with the Scotch authorities in objecting generally to the boarding out of epileptics. He referred to the special enactments of the Scotch law on this subject, and briefly to Mr. Trevelyan's Irish bill, which did not become law, one object of which was to found a boarding-out system in Ireland.

Dr. William Moore said the increase of lunacy in the County Antrim was occupying the attention of a committee as regarded the disposal of harmless lunatics, and the provision of further

accommodation to meet the increase. The boarding-out plan suggested a means of providing for the harmless lunatics without incurring the cost of building a big asylum.

Dr. R. Montgomery said he had had experience of the success of the boarding-out system.

Dr. Doyle mentioned that the son of a patient of his own had spoken of Gheel in the highest terms from personal experience. The charge was £40 a year in his case.

Dr. Conolly Norman, in reply, said there was no doubt that Gheel had done very good work; but there was too much freedom there on the one hand, and too much restraint on the other, and so it was not up to his ideal of the treatment of lunatics. He did not approve of sending lunatics to workhouses, as being institutions with all the faults of the lunatic asylums and very few of an asylum's virtues.

SECTION IN SURGERY.

Meeting of March 28, 1890.

The President, Mr. Meldon, in the Chair.

Cicatricial Stricture of the Œsophagus.—Mr. Kendal Franks read a paper embodying the histories of four cases of cicatricial stricture of the œsophagus. The first case was that of a girl, aged twenty, the details of which were published in the *Medical Press and Circular* in 1882. The treatment employed in this case was forcible rupture of the stricture, with the subsequent daily passage of bougies The treatment occupied over two months. Now, at the end of eight years, she was perfectly well. The second case was that of a lady, aged thirty, who came under treatment in December, 1883. The history of dysphagia extended over nearly fourteen years. The treatment employed was gradual dilatation with bougies, and it occupied nearly seven months. She had enjoyed perfect freedom from dysphagia ever since. A bougie was passed for her about twice a year. The third case was that of a lady, aged forty-three, who came under treatment in June, 1886, for dysphagia, dating back for nearly fifteen years. The treatment adopted was electrolysis, with the occasional passage of bougies. The treatment was employed on sixteen separate days. She had had no difficulty in swallowing since then. The fourth case was that of a railway guard, aged sixty-eight, who came up for treatment on the 17th of December last. The history of dysphagia went back seven or eight years. Two strictures existed—one four centimetres below the upper end of the œsophagus, the other four to six centimetres above the lower end. The treatment adopted was immediate rupture of the strictures, the passage of bougies daily, and electrolysis. The treatment occupied a month. The patient gained twenty-eight pounds in weight in less than three months, and could swallow his food with ease. The passage of a large bougie was employed every second day still by Dr. Ford, of Waterford, under whose care the patient was at present.

The speaker pointed out the remarkable contrast in the duration of the treatment between the cases in which electrolysis was employed and those in which it was not, but that further evidence was required to ascertain if this contrast were constant.

Mr. Hamilton said cases of stricture of the œsophagus were by no means common, and one of the most mysterious problems in surgery was as to how they took place at all. Of the three methods of treatment submitted for consideration in Mr. Franks's paper, he would adopt that of gradual dilatation, or, that failing, then of electrolysis, rather than the method of sudden and rapid dilatation by means of the instrument exhibited.

Mr. W. Thornley Stoker concurred with Mr. Hamilton. The treatment which he had been in the habit of using was that of gradual dilatation, and he condemned that of interual œsophagotomy.

Mr. Edgar Flinn said he saw the second patient whose case had been described. She was suffering from an ordinary catarrh, but she was in perfect health, save nervous debility, being apprehensive of a return of the stricture.

Mr. T. Myles, without questioning the accuracy of Mr. Franks's diagnosis, would feel hardly justified in assuming that all the cases described were cases of purely fibrous strictures. He, too, agreed with Mr. Hamilton as to the inadvisability either of cutting operations on the œsophagus, or of forcible dilatation, as its walls were thin, unresisting, and easily penetrable, even with the point of a comparatively blunt instrument.

Mr. Franks, in reply, said the instrument which he used, dilated to its fullest extent, would not injure any normal œsophagus, as being within the size of the normal œsophagus in health. As regarded diagnosis, the history of his cases differed entirely from that of neurotic cases in which the dysphagia was intermittent; and, as a rule, in œsophageal strictures the diagnosis could not be certain without passing a bougie. He did not think he had been mistaken in his diagnosis, and he had no doubt that the cases were cases of cicatricial or fibrous stricture. The electrolysis facilitated the use of the bougies.

A Rare Case of Congenital Form of Ranula.—Dr. Edgar Flinn said, in a paper read before the Moscow Medical Society, by Dr. N. Muller, on Ranula in New-born Children, he stated that in the foundling hospital at Moscow four or five cases of congenital ranula had been observed during a period of seven years in about eighty thousand children. And the London Medical Record, of December, 1877, mentioned that up to that period there were only two known instances of this affection on record—one published by Dubois in 1833, and a second of more recent date by M. Lombard. Mr. Bryant recorded two cases, both probably, he stated, congenital, and Sir W. Ferguson one.

The case of ranula under notice resembled that class of tumor noticed by Fairlie Clark; it presented some peculiar and interesting features, which were deemed worthy of recording, more especially as the growth was noticed on the second day after birth, and the subject was now nearly twenty-nine years old. The patient was admitted into St. Michael's Hospital, Kingstown, under Dr. Flinn's care. He presented a peculiar appearance; at first sight he gave one the impression that he was suffering from acute glossitis. His mouth was wide open, and it was with great difficulty he could articulate; the tumor very nearly filled the entire cavity of the mouth. The tongue was pushed upward and far backward, and could with difficulty be felt with the tip of the finger. The growth also projected beneath the jaw into the mylo-hyoid space, and assumed an elongated shape. In this situation, being about five to six inches in length, it was hidden from view by the patient's beard, and was as large as a good-sized orange. The projection into the cavity of the mouth commenced to cause inconvenience about eight months prior to the date of his admission, and for over a month he had experienced great difficulty in swallowing; he daily essayed to get some solid food down, but it was quite an ordeal to do so, as it required a good deal of manipulation to get the food to the back of the mouth. There was a continual dribbling of saliva, and he was unable to lie down in a recumbent position for fear of suffocation. On examining the tumor, fluctuation was quite evident in the mass in the mouth, but in the neck it partook of a more solid nature. The treatment that suggested itself on his admission was to aspirate that portion of the mass within the mouth, which was done at once. Nearly fifteen ounces of fluid of a creamy nature was drawn off, and gave him great relief; he could speak more distinctly, but found difficulty in moving

his tongue forward. For a day or so the tumor rapidly filled again in the mouth, and was aspirated a second and a third time, large quantities of a similar fluid as before being drawn off. The mass now on the neck became softer, and deep-seated fluctuation could be detected. It was then decided to lay open the tumor from the neck, which was done by a deep incision, and which gave vent to some five ounces of a thick, brown, pultaceous matter, offensive in odor. The cavity was scooped carefully out and a drainage-tube inserted, and, after a day or so, there was some suppuration and a free discharge of pus. Subsequently the patient left the hospital freed from the unsightly mass that had disfigured him for so many years. The case was considered of interest from the fact of this tumor being so long in existence, the patient being now nearly twenty-nine years old.

Mr. W. THORNLEY STOKER exhibited the photograph of a girl, aged four, who had a congenital tumor occupying the tongue and floor of the mouth to such an extent that she could not shut her mouth since her birth. Having cut into it, he found it was a cyst—a ranula—filled with a thick fluid of abominable odor. He drained it by a large drainage-tube passed transversely through the floor of the mouth below the tongue, but no sooner was the tube taken out than the sac filled again with pus. At length he drained it from the floor under the tongue, and it healed with ease and rapidity. Owing to the fact that the child had never been able to close the mouth, the molar teeth struck each other, while the upper and lower incisors were an inch distant, the jaw retaining its abnormal position. He proposed to put an elastic apparatus on at night, with a view to raise the front of the jaw by gradual pressure.

Mr. HAMILTON also related an instance of the value of treatment by a bold external incision for ranula, emptying the tumor by means of a free incision along the base of the jaw.

Mr. FLINN, in reply, regretted that the urgency of his case at the time prevented him from getting the patient photographed.

LETTERS TO MY HOUSE PHYSICIANS.

By WILLIAM OSLER, M. D.,
BALTIMORE.

LETTER III.

MUNICH, *May 27, 1890.*

DEAR R.: At Zurich we found Professor Eichhorst just about to go off for the day, but he very kindly took us through wards full of instructive cases, among which were very many of pneumonia, which he said was almost epidemic. There are special pavilions for contagious diseases, and we were very much interested to see, for the first time, the cases of phthisis isolated, a plan which had been carried out here for some years. Perhaps in old hospitals with insufficient ventilation this precaution may be necessary, but the experiments of Cornet show that the bacilli are not always present in the dust of wards in which there are patients with phthisis. The question is one attracting a great deal of attention in Germany, and I send you a paper by Professor Finkelnburg, of Bonn, in which he advocates strongly the erection of public sanatoria for consumptives. Another pamphlet on this subject by Cornet—*Wie schützt man sich gegen die Schwindsucht?*—will also interest you. The main point which he makes is the prevention of the desiccation of the sputa by the stringent use of spit-cups and the proper disinfection of the same. Professor Eichhorst's clinical laboratories are large, conveniently arranged rooms, two of which are especially equipped for bacteriological and chemical work. The latter is in charge of a young chemist, not a medical man who makes reports on regular forms. This seems to me a great advantage, particularly when there are elaborate and complicated analyses to be made. Here, too, we found the system of hydrotherapy in use in the treatment of typhoid fever, and the mortality had been reduced to the extremely low point of five per cent.

Professor Klebs was away, but one of his assistants showed us the pathological laboratory. We were also very disappointed not to have seen Professor Forel, who was at the Montpellier festival. We spent a delightful day with Professor Gaule, the physiologist. He first demonstrated some of his remarkable histological specimens, particularly a series of the frog's testis at different months of the year, prepared by his method, which you will find in any of the recent histological manuals. Not only in the testis, in which, in certain animals, we should expect marked seasonal changes, but in other organs, such as the liver, he holds there are variations in the constitution of the cell protoplasm throughout the year. Mrs. Gaule, an American lady and a well-known histologist, is an active co-worker in the microscopical department of the laboratory.

I was still more interested in the brain of a dog which had had a remarkable experimental history. The center for the left foreleg was first destroyed, with the result of a paralysis, which gradually disappeared. Then the corresponding center in the right side was destroyed, with the effect of producing paralysis of the forelegs on both sides and loss of intelligence, so that the dog lost knowledge of his tricks and was, in fact, like a puppy. He regained power in the legs and was gradually re-educated, with, however, great trouble, by one of the lady students of the laboratory. Then a portion of the brain on the right hemisphere behind the left-leg center was removed, with the result of paralysis of the leg, after which the animal was killed. The experiment is chiefly of interest as showing substitution of function somewhat similar to that which took place in Barlow's celebrated case of aphasia in which the patient, after recovery from the effect of an embolus on the left middle cerebral, gradually regained the power of speech, which was again lost in a second attack, when an embolus plugged the artery of the right side.

In lecturing, Professor Gaule uses the projection lantern very frequently, and has it so arranged that the image is thrown from behind the lecture-room upon a glass screen behind the movable blackboard. I have never seen microscopic objects so beautifully projected, and the technique was carried to such perfection that even the movement of the ciliated epithelium could be seen from all parts of the room.

Munich is the largest of the three Bavarian schools, and I was particularly anxious to see the arrangements of the medical clinic, which were reported to be unequaled in Europe. Unfortunately, we came in the midst of the Whitsuntide holidays, when the lectures had ceased and the laboratories were deserted. Professor von Ziemssen (whose name is one of the most familiar to the profession of English-speaking countries) was at home, and very kindly showed us the clinical institute, which is attached as a wing to one side of the main hospital building. It was erected in 1878, and when I tell you that the cost was over $50,000 you will have some idea of its extent. The ground floor is devoted largely to outdoor medical work—the ambulatorium, as it is called—and to rooms for the assistants and docents, with suitable arrangements for demonstrations and classes. The second floor has the professors' private rooms, the library, a room for the records, the auditorium, a large chemical laboratory, and a series of four rooms communicating with each other for microscopical, bacteriological, and electrical work. The institute is unusually rich in apparatus for experimental research, and going from room to room and listening to the description of treasures of all sorts for clinical investigation, I realized, as never before, what the Queen of Sheba felt when she said, after seeing the treasures of Solomon, "that there was no more spirit in her." The files of the *Deutsches Archiv für klinische Medicin* for the past twelve years show a record of good work of which the director of the institute may well feel proud. The hospital notes are very carefully kept and pigeon-holed, first by months, then at the end of the year bound loosely according to the disease. With an index of the names and another of the diseases, any case can in this way be referred to in a few minutes. Of models we were shown a number illustrating the alterations in position and size of the stomach—some in plaster, others

in papier-maché. Dilatation of this organ is very much more common here than with us, owing to the enormous quantities of beer consumed. Some of the men connected with the breweries are said to drink from twelve to twenty litres daily. Voit makes the statement that the average consumption of beer in Munich is two litres and a half per capita daily. It is cheap and good, a litre costing only twenty-four or twenty-six pfennigs; and when one sees the crowded state of the beer-houses at all hours of the day, Voit's estimate appears very moderate. The influence of the beer is shown in another way—viz., in inducing hypertrophy of the heart, upon the frequency of which in Munich and on its association with beer drinking Professor Bollinger has recently written. Von Ziemssen thought that it was the combination of hard work with heavy drinking that rapidly raised the aortic blood-pressure and was so dangerous. The cases were met with chiefly in those whose occupations necessitated great muscular exertion, such as draymen and porters. Though less common, these cases are by no means rare in our large cities among men who work hard and who at the same time drink heavily.

Within the past ten years Munich has gradually acquired a thorough drainage system, and we were shown a set of charts in course of preparation for the Berlin Congress, illustrating the remarkable reduction in the number of cases of typhoid fever. In certain sections of the city, formerly much affected, the disease is now almost unknown. The chart showing the hospital experience during this period follows the same falling curve. Munich is now one of the healthiest of the continental cities, whereas it formerly had an exceptionally high death-rate, particularly from zymotic diseases. The medical wards are in the part of the hospital adjoining the clinical institute, but, as the building is very old, the arrangement of the rooms is not very satisfactory. A new surgical department is nearly completed. Professor von Ziemssen lives in a separate house within the hospital grounds, so that he is not far from his work and can readily, as he expressed it, stand like a colossus with one foot in the wards and the other in the laboratory. It is a pleasure to think that one who has done so much for the profession is so well provided for and has everything that a teacher or investigator could desire or deserve.

We took advantage of the vacation and went to Ober-Ammergau to see the Passion Play. The crucifixion scene is frightfully realistic, every detail represented, even to the piercing of the side, from which the blood—an aniline fluid, I suppose—flows freely. A problem, much discussed of old, why Christ should have died after so comparatively short a time upon the cross seemed to my mind to receive its solution in the mental and physical exhaustion consequent upon the trials of the preceding twenty-four hours. There is a remarkable book dealing with this subject by Dr. Stroud, *Theory of the Physical Cause of the Death of Christ*, in which he argues that it was due to rupture of the heart; but this would be highly improbable in a vigorous, healthy man of thirty-three.

In looking over the Passion Play literature, we find a long account of the performance in 1830 by Oken, the anatomist, and it was extremely interesting to find that this description of the play as given sixty years ago might have been written of this year's representation.

Reports on the Progress of Medicine.

OBSTETRICS.

By ANDREW F. CURRIER, M. D.

The Practical Means employed to provoke Premature Labor (Boissard, *France méd.*, Jan. 10, 1890).—The object of all the agents which are used to excite premature labor artificially is to provoke uterine contractions, and all means which are used should permit the least possible deviation from normal labor. Among the agents which may be used are: 1, uterine douches; 2, the introduction of dilating bodies into the uterus; 3, the introduction of exciting bodies; 4, the introduction of bodies which are both dilating and exciting. The dilating or exciting bodies are represented by tents of sponge or laminaria, bougies, bags, or balloons. Uterine douches were frequently used a few years since. Such a method should be rejected because it is slow, unreliable, and dangerous. Many serious results have been recorded in connection with its use. Of the tents it is difficult to render those of sponge aseptic, but those of laminaria may be made quite aseptic by dipping them for twenty-four hours in an ethereal solution of iodoform. It is easy to introduce them, but they are liable to slip out unless secured by a vaginal tampon. Perforation of the membranes is an infallible way of bringing on labor, but it is very slow, and favors vicious presentations. The use of the bougie is also slow as to its results; it may be inefficacious and may be attended with accidents.

Of all the excitant and dilating methods, the author gives preference to the instrument of Tarnier or to that of Ribes. The former is a rubber balloon and will usually do its work in from twenty to twenty-four hours.

Ribes has also devised a balloon 30 to 33 centimetres in circumference and holding 640 grammes of liquid. It will dilate not only the neck, but the entire vulvo-vaginal canal. Two facts have been noticed in connection with the use of this dilator—rapidity of delivery and constancy of results, the average duration of labor in observed cases being twelve to fourteen hours. The material from which it is made is thin, and it may easily be introduced with the forceps. The possible inconveniences in its use are the necessary rupture of the membranes, the breaking away of the placenta, procidentia of the limbs and cord of the fœtus, and the displacement of the fœtus. One or another of these accidents occurred in one third of the cases treated by Ribes's method, though mother and child were saved in every case. The author concludes as follows:

1. Of all the means which have thus far been devised for producing premature labor, the balloons of Tarnier and of Ribes are the most efficient.

2. In spite of the inconveniences or difficulties which may result from the introduction of a large balloon into the uterine cavity, the instrument of Ribes may be depended upon to give the most rapid and constant results.

Extra-uterine Pregnancy (Pinard, *Concours*, Dec. 28, 1889).—Three cases are narrated in which operative procedures were resorted to, all of them ending in recovery. This question is propounded: An extra-uterine pregnancy has proceeded almost to term before it is recognized the fœtus is dead—what is one to do? One can not advise indefinite expectancy. It would be dangerous to reckon upon the transformation of the fœtal sac into lithopædion, for such a change is of rare occurrence. If intervention is determined upon, when should it take place? Most authors caution against waiting for the explosion of accidents which attend suppuration. On the other hand, should one operate as soon as possible after the death of the fœtus? The author agrees with Kaltenbach, Fraenkel, Litzmann, Werth, and Maygrier that one need not operate immediately after the death of the fœtus unless there are special indications therefor. Six weeks after the death of the fœtus the circulation within the fœtal sac ceases, and then it will be safe to operate; earlier than this there is great danger from hæmorrhage. There are two methods of operating—by elytrotomy, the cyst being opened through the vagina, and by laparotomy. The first should be preferred if the cyst dips deeply into the pelvis, the bladder and uterus being displaced laterally and the placenta not being implanted in the lower part of the cyst. In other cases laparotomy should be practiced. If laparotomy is performed and the cyst is found to have extensive adhesions to the intestines and bladder, it is better to suture the cyst to the edges of the abdominal wound and then open it and extract the fœtus. If the placenta does not come away readily, it is better to leave it *in situ* and allow it to come away spontaneously. The cord may be removed at its placental insertion, and the cavity may then be irrigated with a warm saturated solution of β-naphthol. The wound should then be closed except for a space six or seven centimetres in length, through which the placenta may protrude. Two large drainage-tubes may then be placed in the lower angle of the wound, and the latter be covered with carbolized gauze. Over this an abundance of cotton should be placed, and the entire dressing should be secured with a pressure bandage. The cavity of the cyst will contract rapidly, and in fifteen or

twenty days it will have disappeared. In two months the entire wall of the cyst will have disappeared.

Hot Irrigations subsequent to Parturition (Deipser, *Jour. de méd*, Feb. 9, 1890).—There are obstetricians who think that if a labor has not called for repeated examinations or operative treatment there is no necessity for antiseptic treatment of the genital passages, on the ground that no irrigations are indicated if there is no suspicion of infection. But it is better that the accoucheur should act as if accidents were about to happen after labor, and take the necessary precautions. Should he wait three or four days until accidents have occurred, he is liable to reproach. What agent should be preferred for irrigating purposes? Sublimate has given rise to accidents with some, though it has given excellent results to others. Carbolic acid is no longer popular with physicians or midwives. Creoline seems to meet with general approval at present, and should be used immediately after labor and for the six succeeding days in solutions with a temperature of 50° C. The temperature of the water in itself opposes the multiplication of germs. The injection current will wash away blood-clots from the uterine mucous membrane and any other foreign matter which may be there. As antiseptic substances are ordinarily used, the injected solutions are at the temperature of the blood. This is not sufficiently elevated and may prove dangerous by favoring relaxation of the uterus. If the injected solution has a temperature of 50° C., it will produce irritation and uterine contraction. One can therefore use these injections either to stop post-partum hæmorrhage or to increase the efficiency of uterine contraction. A portion of the water used in vaginal irrigation will penetrate the uterus. It will do no harm, but, on the contrary, will favor the production of uterine contraction, and will also assist in dissolving and washing away fragments of tissue which should have been expelled in the course of labor.

The Cæsarean Operation and its Clinical Results (Martin, *An. de Obst., Gin. y Ped.*, November, 1889).—The following conclusions are reached by the author:

1. One should insist, as a hygienic measure, upon the medical supervision of all cases in which, by reason of pelvic disproportion, it may be necessary to resort to Cæsarean section. In such cases it may be feasible to resort to premature artificial labor, with the birth of a viable fœtus.

2. Among modern operations the Cæsarean section should be esteemed of primary importance in its varieties—the Sänger and the Porro-Müller operations.

3. Among all parturient women with contracted pelvis, in whom exist indications for operative procedure, preference should be given to the Cæsarean operation above the different methods of embryotomy, as it is more humane and offers better results for both mother and child.

4. The Cæsarean operation should be performed after dilatation of the cervix and prior to rupture of the amniotic sac, such a plan offering the best prospects of success.

5. Listerian methods should be followed with all care whenever the Cæsarean operation is performed.

A statistical table is published with this paper, which shows that seventy per cent. of the improved Cæsarean operations have resulted successfully.

The Use of Anæsthetics by Midwives (Budin, *Concours*, Feb. 15, 1890).—A report upon this subject was recently read before the Paris Academy by the author. The rôle which has heretofore been played by midwives in the propagation of puerperal fever was first referred to, and then the question would naturally arise, What antiseptic, if any, should be placed in their hands? for epidemics of puerperal fever are more or less prevalent in the practice of midwives, and antiseptics are the proper means for attacking the disease. The first suggestion would be that boiled water should be used, but this would not be sufficient to destroy germs, even supposing that the midwives were sufficiently careful in cleansing their hands, forearms, and nails. Hence it would seem necessary that midwives should be allowed or required to use antiseptics. There are many antiseptics, however, and it is expecting too much that midwives should be acquainted with their varying power and the different ways of using them; besides, many of them consider such agents useless, and would not employ them unless required to do so. Their use should therefore be simplified as much as possible, and the commission which took the matter into consideration at the request of the official authority recommended that only one antiseptic be given to midwives, and that this should be as efficacious as possible without exposing the midwives or patients to intoxication or cauterization. It should also be cheap and easily kept and carried. The author considered in succession the merits of boric acid, creolin, naphthol, carbolic acid, and sublimate, the last of which was preferred, with the objection, however, that in certain doses it was toxic and might injure the patients. In answer to this objection, it may be said that very few people are excessively sensitive to sublimate when used in the form of vaginal irrigation, and the author, in an extensive experience with it since 1882, has seen nothing severer than an occasional attack of gingivitis or erythema. Of the sixteen fatal cases which have been reported as resulting from its use, the influence of sublimate in some of them is questionable. In fourteen of them intra-uterine injections had been made with solutions of 1 to 1,000 or 1 to 2,000; in only two of them had there been no intra-uterine injections. In the latter there had been extensive rupture of the perinæum, and irrigation with a 1-to-1,000 solution of sublimate was practiced during the operation of suturing it. In some of the cases there had been nephritis, or profound anæmia fram hæmorrhage, or retention of the placenta within the uterine cavity, and thus intoxication from mercury had been favored. Intra-uterine injections should not be made by midwives, and, should fever or any other abnormal condition follow the parturition, the services of a physician are at once to be procured. Compared with carbolic acid, it may be said that the effect of sublimate upon the new-born is far more favorable.

The Action of Hot Water on the Uterus during the Pregnant and Puerperal States (Pinard, *Jour. de méd.*, Feb. 9, 1890).—This subject includes the use of hot water during pregnancy, during labor, during delivery, and duriug the involution of the uterus.

The ancients forbade the use of baths during pregnancy from fear of abortion or premature labor. Kiwisch proposed a method to do away with this traditional fear. Investigations made during the last few years have shown that water at 45° to 50° C., while acting as an energetic stimulant to smooth muscular fiber, can not produce contractions sufficient to interrupt the course of pregnancy. If injections of hot water are used in such a way that traumatism is not produced, there need be no fear of provoking labor pains. Hence the elytritis which may exist during pregnancy can and ought to be treated by irrigation with medicated hot solutions.

Hot injections, whether intravaginal or intra-uterine, have a marked effect upon the contractility of the uterus during labor. The latter have a more decided and intense action than the former. Hot water as an oxytocic does not modify the physiological characters of the uterine pains. The contractions which follow the use of vaginal irrigation have a more marked amplitude and longer duration, but are not more frequent in the majority of cases. They are more efficacious, however, and shorten labor. They should, therefore, be used in cases in which the period of dilatation lasts longer than the average. Especially should they be used in cases in which the death of the fœtus and the rupture of the fœtal sac demand a rapid expulsion, and this rule applies as well for cases of abortion as for those of labor at term. Hot irrigations have the same action during the period of delivery as during the precedent period of labor. To their oxytocic action is added the hæmostatic. If to a woman who is attacked with uterine hæmorrhage one gives an intra-uterine injection with water at 46° to 50° C., the uterus will contract energetically and by and by the water will return from the uterus uncolored. Of course the uterus must first be relieved of all clots. Hot water also exercises a decided effect on the uterus during the period of involution, the latter process being hastened by its use. The metrorrhagia which may occur at this period will yield to irrigations with water at 45° C.

Alcohol in the Treatment of Puerperal Fever (Martin, *Ctrlbl. f. Gyn.*, 1889, No. 31).—This paper contains an account of eighteen cases, —fifteen of septicæmia and three of pyæmia—in which alcohol was administered as a means of treatment in accordance with the rules recommended by Breisky and Conrad in 1876. All of the patients were seen in private practice and had been treated locally or by the internal use

of antipyretics before they came under the author's observation. When seen by him they were in a very bad condition, the prognosis being very unfavorable. Alcohol was prescribed for all of them in the form of brandy, rum, champagne, burgundy, etc. In all cases the alcohol was well tolerated. Of the eighteen patients, thirteen recovered, three died from puerperal infection, one of the other two from phthisis, and the other from pulmonary œdema. Martin believed that the benefit of the alcohol consisted rather in the stimulation of the heart than in the reduction of the temperature. The alcohol was used as an adjuvant to local treatment and to the use of antipyretics, and it was found that it could be used in large quantities without fear of intoxication, and in conjunction with milk, eggs, etc. Martin concluded that alcohol was a most valuable remedy in puerperal fever which could be used in desperate cases without fear of disagreeable secondary results.

In the discussion of the paper Schülein stated that he had used alcohol in large quantities in the treatment of puerperal fever and with good results.

Gottschalk referred to the free use of alcohol in the treatment of five cases of puerperal fever under his observation; four of them were cases of septicæmia and one of pyæmia. In all the cases there was diffuse peritonitis. After having once disinfected the genitals thoroughly in these cases, local treatment was suspended, the treatment being limited to large doses of alcohol and nitrogenous foods. The alcohol was given in the form of brandy, 500 to 1,000 grammes being given in the course of twenty-four hours. To allay vomiting, cocaine was given with good result. In one of the cases baths were administered, resulting in the lowering of the temperature and improvement of the appetite. In another patient the alcohol produced intoxication, with loss of consciousness and delirium. It was then dispensed with, strong coffee was administered, an ice cap was placed upon the head, and the bad symptoms disappeared, the fever and peritonitis gradually yielding.

Olshausen did not think it had been clearly demonstrated that alcohol was essential in puerperal septicæmia, especially since he had seen severe cases of the disease cured without its use. In cases in which there was no diffuse peritonitis one could not say whether a cure was due to the therapeutic agent employed or to the fact affection was mild in character, and, if there were diffuse peritonitis, alcohol was of as little value as all other remedies. In the last-mentioned disease baths were unsuitable, for every movement of the patient was attended with pain. In cases of prolonged or chronic pyæmia with persistent elevation of the temperature baths might be used, and alcohol would supply sufficient force to enable the patient to resist the disease. He did mean to discourage the use of alcohol in cases of acute puerperal septicæmia.

The Microbiology of the Cervical Canal in Endometritis (Solovyoff, *An. de Obst., Ginecop. y Ped.*, February, 1890).—The author's investigations were made in connection with Slavjansky's clinic to determine whether the genital canal in women contained pathogenic microbes. Experiments were made upon forty-five women and the following conclusions were reached:

1. In the great majority of cases of endometritis, but not in all, there are micro-organisms in the cervical canal.

2. In cases of acute puerperal endometritis there are pyogenic microbes in the secretions of the cervical canal.

3. In the secretions of chronic cervical endometritis inoffensive microbes are far more frequently found than morbific ones.

4. The clinical investigation of cases of chronic endometritis will not enable one to distinguish cases in which the microbes are pyogenic from those in which they are not.

5. Animals which are inoculated with pyogenic microbes show, in some cases, morbid conditions in which the virulence of the microbes has not been attenuated.

6. It must be admitted that there is a possibility that these microbes will infect the organism when the conditions favor their penetrating the tissues.

7. As in some of the cases in which there are pyogenic microbes there exists the possibility of pregnancy and of parturition at term, and as at this time and during the puerperal period there may be conditions favorable to infection, we must admit the possibility of infection by microbes existing in the genital canal prior to this period.

8. External antisepsis and antisepsis of the individual do not offer a positive assurance that the parturient and puerperal conditions will be aseptic.

Ectopic Pregnancy (Tait, *Ctrlbl. f. Gyn.*, April 12, 1890).—Tait prefers the above name to the old one, extra-uterine pregnancy, because the so-called interstitial form, as well as that form which occurs in one horn of the uterus, is not strictly extra-uterine. The author thinks that the fertilization of the ovum takes place, as a rule, in the uterus, and that it can only attain to those portions of the genitals which are situated higher up when the normal ciliated epithelium of the tubes is destroyed. The office of this epithelium is not only to propel the ovum forward into the uterus, but also to prevent the entrance of the spermatozoa into the tubes. Hence only when, as a result of some precedent morbid process, the ciliated epithelium is injured or destroyed, can spermatozoa get into the tube and fertilize an ovum. The mucous membrane of the tube then having become similar to that of the uterus, the ovum is enabled to imbed itself in it. Many cases give evidence that a desquamative salpingitis has been present. In some cases the condition becomes suspicious if the woman has been sterile, or if several years have elapsed since her last pregnancy. Tait doubts the possibility of a true ovarian pregnancy, but, if it should occur, its course and danger would not differ materially from those of tubal pregnancy.

Pregnancy may take place in either of the three divisions of the tube, the interstitial, the middle, or the infundibulum. The interstitial form is rare, Tait having seen but one case and knowing of but six in England. Its course is always fatal. One does not know anything of its existence until rupture occurs, which may not take place before the sixth month, and usually does not before the fourth month. The loss of blood is then so great that death usually results in a few minutes; the rent is also a large one, being 10 or 12 centimetres long. The only means of saving life would be the performance of hysterectomy, and the prognosis would be bad even if one were promptly at hand to perform it. Rarer still is the variety in which there is development at the infundibulum, only three specimens of this variety being in the Hunterian museum. With regard to the third variety, in which the middle portion of the tube is involved, it is important to consider the nature of the peritoneal covering. The distensibility of the tube is very limited, and it becomes still less distensible owing to the spongy nature of the placental structure. Rupture does not take place later than the twelfth week. According to the location of the placenta will the rupture take place into the abdominal cavity or between the layers of the broad ligament, and this fact furnishes a means of differentiation between two different varieties. In the first variety the hæmorrhage will be persistent, in the second it will usually cease. There will be many more favorable conditions in the latter than in the former variety, for death will usually end the scene before the physician can arrive. As to diagnosis, the two varieties of rupture and hæmorrhage are easily distinguished. With the bleeding into the abdominal cavity there is only an illy defined feeling of fluctuation, and in Douglas's space there is a soft swelling. With the intraligamentous hæmorrhage, on the other hand, there is a circumscribed round tumor in the pelvis, which may reach to the navel, and perceptibly fluctuates. The vaginal walls and the whole pelvic cellular tissue are as hard as a board. In severe cases the pressure of the extravasated masses of blood will cause a stricture of the rectum which may require months for its healing. If we bear in mind the general symptoms of the early stages of pregnancy, as well as the irregular but frequent hæmorrhages which occur with this condition, we will be able to determine the diagnosis. Subsequent rupture of this hæmatocele will produce phenomena which may lead one to suppose that the hæmorrhage has been direct from the vessels into the abdominal cavity. Should one puncture such a hæmatoma in the broad ligament, the pressure derived from the blood would be removed and the hæmorrhage would begin anew. In about one tenth of the cases the hæmorrhage is slight, the blood is quickly absorbed, the fœtus develops to the fourth or fifth month, then dies, and then is absorbed or undergoes suppuration. Then comes perforation into the rectum or bladder, with discharge of pus and fœtal bones. The fœtus may, however, go on to complete development, the peritonæum being enormously distended. The peritonæum may be raised in the course of the develop-

ment of the fœtus from the anterior wall of the uterus, the bladder, and the abdominal parietes, nearly to the navel. In such case one should operate and endeavor to obtain a living child. Such children may be well developed, and Tait has rescued three in this way. Electricity may be used if tubal pregnancy can be diagnosticated before rupture has occurred, but he believes this is seldom possible, and he has never been able to do it. He has always been summoned when rupture has occurred and the patient is in collapse. If at such a time the hæmorrhage is intraperitoneal, electricity will not arrest it. If it is intraligamentous, then perhaps no interference will be necessary. If the result would be fatal without interference, then one must act in accordance with simple surgical principles—that is, seek for and tie the bleeding vessel as soon as possible.

Obstetric Operations in the Practice of Midwives (Ahlfeld, *Ctrlbl. f. Gyn.*, April 12, 1890).—The question as to the operations which midwives should be allowed to do is one which should be discussed among physicians, and rules should be laid down which the midwives should not transgress. For the future it seems to be agreed, at least in certain parts of Germany, that midwives may manage breech presentations under certain restrictions—that is, they may superintend the birth of the arms and the head. It is possible that this is too great a concession, as the statistics of midwives' practice show that the number of stillborn infants in breech presentations is quite large. The delivery of the breech and the feet should not be attempted by midwives. Dragging upon the presenting feet, and so hastening the progress of labor, may seem proper enough to a midwife, but it may be an element of danger by bringing the head into an unfavorable position, or by producing severe lesions of a cervix which is not yet sufficiently dilated, or by inducing too great constriction of the child's neck and producing its death. The only condition which would justify the midwife in taking this step would be profuse hæmorrhage, with placenta prævia and a well-dilated os. Even in such cases it would probably be better that the midwife should merely bring down a foot, so that the breech of the child might act as a tampon for the bleeding area.

Still more important is the question as to the wisdom of allowing midwives to perform internal version and removal of the placenta. In the author's section of country the statistics of midwives' practice show that version has seldom been done by them. This is partly owing to their hesitancy in undertaking such an operation, and partly owing to the ease of obtaining skilled professional assistance. The author's opinion is that such work should not be done by midwives, and the operation is usually easier if the midwife has not complicated matters by attempting to perform it. There are exceptions, of course, in very isolated places, where skilled physicians can not be had. Midwives should also not be allowed to separate the placenta from the womb. This may result in a few deaths from hæmorrhage, but probably far fewer than if midwives were allowed to use their own discretion in such matters.

Investigations concerning the Quantity of Hæmoglobin in the Blood during the Last Months of Pregnancy and during the Puerperium (Reinl, *Deutsche med. Zeitung*, No. 27, 1890).—The author's investigations were made upon fifty-one hospital patients who were pregnant, and were compared with investigations upon ten healthy non-pregnant women. The spectrophotometer was used for the determination of the hæmoglobin, and the blood used for experimentation was diluted one hundred and fifty times with a ten-per-cent. solution of sodium carbonate. The hæmoglobin in the healthy non-pregnant women was found to be 12·24 per cent. In ten of the pregnant women the average hæmoglobin content was 12·99 per cent. In the remaining forty-one the average was 10 per cent. In order to ascertain the relation between the hæmoglobin and the red corpuscles, the latter were counted in the ten non-pregnant women and found to average 4,797,300 to the cubic centimetre of blood. This number was exceeded in twenty-one of the pregnant women, the average being 5,156,000. This high average pertained to pregnant women who were in favorable conditions of life up to the time when they were received at the hospital. The investigations showed conclusively that those women who were well nourished—that is, received an abundance of albumin during their stay in the hospital—always experienced an increase in the quantity of albumin as well as in the red corpuscles in their blood. Chloro-anæmic conditions were not met by the author in this investigation; but simple anæmia in pregnant women may easily develop under the influence of social and individual conditions, and there is always a lessening in the number of red corpuscles *pari passu* with the lessening of the hæmoglobin. The author disputes the theory that pregnancy is to be considered in the light of an anæmia-causing condition. It was always demonstrated that those who came into the hospital in an anæmic and hungry condition lost their anæmia under the favorable dietetic and hygienic conditions to which they were there subjected. Simple oligochromæmia does not exist during pregnancy, but it does exist in combination with oligocythæmia. In thirty-seven cases which were investigated subsequent to the parturition, the hæmoglobin was found diminished in twenty-one, in two it was unchanged, and in fourteen it was increased. The changes in the number of red corpuscles in these cases were for the most part co-ordinate with the changes as to hæmoglobin. The lessening of the hæmoglobin, which was observed during labor in twenty-one cases, was changed to an increase in seventeen of the cases on the sixth or seventh day of a normal puerperium. The red corpuscles increased similarly in number. The foregoing results are not offered as absolutely typical, since the influence of the hospital may have had some bearing in the case.

The Prognosis as to the Probability of Pregnancy following the Conservative Cæsarean Section (Torggler, *Prag. med. Woch.*, No. 13, 1890).—In comparing the results of the conservative Cæsarean section with those of such operations as perforation and the induction of premature labor, one must regard not only the facts as to mortality and morbidity, but also the question of subsequent fertility, which, according to some authors, is very unfavorably influenced by the Cæsarean operation. On May 13, 1889, the author induced premature labor at the thirty-fifth week of pregnancy upon a woman upon whom Schauta had performed the Cæsarean section December 1, 1885. This case suggested the question of the probable prognosis as to subsequent pregnancies following the performance of such operations. To the table of Caruso, containing histories of 135 such operations, the author adds 36 cases, the operations in 12 of the cases being in the years 1888 and 1889, and in 24 in previous years. Of these 171 cases, 132 were reported cured, and of the latter number 3 died shortly afterward from causes independent of the operation. In 5 others pregnancy was an impossibility because of certain complications. There were, therefore, 124 women who were capable of subsequent pregnancy. In this number 13 conceptions have been reported occurring in 12 women. This would signify a fertility of 9·6 per cent. in the course of seven years, while, according to Mataeus, eleven times as many conceptions occurred in a similar number of women who were subjected to the operations with which the Cæsarean section is here compared. With women who have undergone the latter operation there is always the fear of having it repeated, which operates against renewed conception. But most of the women in this table were single, only 43 being married. Of these 43 women, 4 died as the result of the operation, and 1 was insusceptible of pregnancy. Among the remaining 38 there were 9 pregnancies—that is, a fertility of 23·6 per cent. From these figures it would appear that fertility after Cæsarean section is not greatly impaired. The prognosis as to a possible future pregnancy may be modified by the choice of material for suturing the uterine wound. Fehling's opinion is that conception is less likely to recur when silver wire is used for the sutures, but the author shows that this view is incorrect. In the 171 cases in the table silver wire was the suturing material in 43, and catgut and silk in 127; in the remaining case the material is not stated. Of the 127 cases, 28 died from the operation, 1 died 87 days afterward, and 4 others were insusceptible of conception. The question as to the influence of suturing material is therefore limited to 94 cases. Of this number, pregnancy recurred in 5, a fertility of 5·3 per cent., or, taking only the married women, a fertility of 12 per cent. Of the 43 cases in which silver-wire sutures were used, 30 were susceptible of conception, and among this number there were 8 pregnancies, a fertility of 26·6 per cent., or 46·1 per cent. if only the married women are considered. This is directly opposed to Fehling's theory and seems to show, on the contrary, that silver-wire sutures are favorable to conception, the reason probably having something to do with the condition of the scar in the uterus.

The author also touches upon the dangers which may ensue when

pregnancy and labor recur after Cæsarean section. Judging from the small quantity of material at hand for the analysis of this question, the danger is not materially increased. Perhaps the greatest danger is from stretched or tense adhesions between the uterus and its surroundings. These are less numerous with the use of silver sutures than with silk or catgut.

Miscellany.

On the Strumous Diseases of Childhood and their Relation to Tubercle.—The following is an abstract of a paper prepared by Dr. Thomas More Madden, of Dublin, for the recent meeting of the British Medical Association:

During a long experience as physician to the first hospital for diseases of children established in Ireland, with which I have been connected since its foundation in 1872, the increasing prevalence of the strumous and tubercular diseases of childhood has been constantly brought under my clinical observation. The intimate connection and relation between these conditions was pointed out nearly a quarter of a century ago in my work on *Change of Climate*, and was discussed in a paper of mine in the *Transactions of the International Medical Congress* of 1871, as well as last year in my article on Puberty, in Dr. Keating's recently published American *Cyclopædia of Diseases of Children*. I refer to these dates merely as evidence that the views embodied in the following brief recapitulation were not hastily formed nor without some experience of the subject referred to. The increasing proportion of strumous and tubercular affections which has been observed of late years in my wards in the Children's Hospital is probably largely ascribable to the faulty dietetic and hygienic management of early childhood, and to the general substitution of artificial, and in many instances very unsuitable, preserved or tinned preparations for that natural or fresh milk which, in my opinion, is essential for the healthy nutrition of children. As I formerly pointed out, and the observation is now more applicable than was the case ten years ago, the acute forms of tuberculosis common during childhood resemble the infective diseases in their origin from a specific germ, whether generated in the body or introduced from without. The latter is probably the case in the tubercular diseases prevalent among the children of the poor, in whose dietary various forms of preserved milk foods now enter largely, as it seems difficult to conceive any certain guarantee that the cows furnishing the supply may not, in some cases, suffer from *Perlsucht*, this disease being very prevalent and not materially affecting the quantity of milk. More recently Professor Bollinger has shown that milk may prove infectious whether taken from cows suffering from general or local tuberculosis; in his experiments only a few drops of undiluted milk from a tuberculous cow proved sufficient to produce miliary tuberculosis in animals. Be the pathogenesis of tuberculosis what it may, however, there can, I think, be no question as to the fact that it is most frequently developed in patients who bear in their general constitutional condition, and more especially in their glandular system, the obvious imprint of the strumous diathesis. Nor is it to be wondered at that in children thus constitutionally enfeebled the struggle for existence between the invading specific micro-organisms and the blood corpuscles or leucocytes should almost invariably so speedily terminate in the fatal victory of the prolific bacilli of tubercle.

The Application of the Vichy Waters.—Dr. Durand-Fardel says that in gout the results to be expected, namely, diminution in severity and postponement of the attacks, are better assured the more robust and healthy the constitution of the patient, and the earlier the attack is anticipated by beginning the treatment. In uric-acid gravel, cessation or amelioration of nephritic colic is accomplished, provided the kidneys are intact. The calculi become smaller or even disappear, and thus are eliminated without provoking painful symptoms. Visceral obesity, that is to say, of the chest or abdomen, is very positively relieved. The effect is less pronounced upon the accumulation of fat in the peripheral regions. In diabetes, especially in alimentary diabetes and in those forms associated with obesity, rapid improvement of all the symptoms is effected, together with a considerable reduction or disappearance of the glycosuria. A subsequent reappearance of the latter symptom in constitutional diabetes does not in general reproduce the previous disturbance of health, which may perhaps remain in a satisfactory condition for a very long time, provided the treatment is repeated occasionally. In biliary calculi and hepatic colics considerable improvement is the rule, and frequently a complete cure is obtained. The same is true in simple congestion of the liver, chronic hyperæmia, and the early stages of cirrhosis of alcoholic or malarial origin or dependent upon venous stasis of the abdominal viscera. In malarial cachexia or in that observed in warm climates, in the intestinal catarrh of warm climates, and the sequelæ of dysentery, the waters act beneficially, also in dyspepsia of the atonic variety or that caused by insufficient secretion of the gastric or intestinal glands. A resolving action is exerted upon most of the congestions of the abdominal or pelvic regions, with the exception of scrofulous adenitis, on congestion of the spleen, and on simple congestion of the walls of the stomach (and also on simple ulcer of this organ), on such intra-abdominal tumors as are capable of undergoing resolution, on iliac and circum-uterine abscesses, and also on congestion of the uterus.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

A CLINICAL LECTURE,
DELIVERED AT THE PHILADELPHIA HOSPITAL.

By ERNEST LAPLACE, M. D.,

PROFESSOR OF PATHOLOGY AND CLINICAL SURGERY IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA; VISITING SURGEON TO PHILADELPHIA HOSPITAL, ETC.

LECTURE II.

REPORTED BY WILLIAM BLAIR STEWART, M. D.

LATER on in the hour I will operate in two cases, one of which will be a case of skin grafting, according to the method of Thiersch, for two ulcers of the leg, while the other will be for the removal of a number of venereal warts from the penis of a man who is suffering with gonorrhœa. Before speaking of these cases I thought I would take this opportunity of addressing you on a question of vital importance in pathology, and to bring into a nutshell and have in a tangible condition what is known of the ætiology of the affection we call cancer.

Cancer, a thing of such dread to all who are acquainted with it, a thing so difficult to diagnosticate and treat—cancer, the bugbear of the medical student, especially when called on to distinguish between it and sarcoma and amyloid growth, etc. To begin with what we know about cancer. The word cancer means simply a crab, so named by the ancient pathologists from its eating or gnawing. At the present time it means nothing else than a hyperplasia, or excessive development, of the cells in a particular part of the body. Now, these cells may either grow on the surface and bulge out, or they may grow on the surface and dip into the tissues. According as they do one or the other, they are benign or malignant growths. Let us say, by way of illustration, it began on the surface of the skin in the epithelium. You all have been out rowing, and have noticed how callous your hand would become and how here and there was a "water-blister." The oar acts as an irritant to the skin, and a congestion and hypernutrition is the result; the epithelial cells proliferate, accumulate in the one spot, and there is a tumor or callus, under which may be found blood serum, which, being absorbed, leaves thickened epidermis.

On the other hand, the man is a smoker and smokes a pipe. The pipe always rubs the same spot. That man comes from a family of cancerous ancestors, and has a suitable soil or predisposition to cancer, if the chances are given for an irritant to enter the tissues. The man may have an abrasion on his lip; the pipe irritates it and causes a hyperæmia. Furthermore, there is another element that comes in, and this is a micro-organism. I can not prove to you that this is the case, nor can I show you the germ, but it is allied to the germs that we know are the cause of other affections. In the case of the thickened epidermis of the hand, and when we have a corn on our foot, we have an irritant acting from without; but in epithelioma the irritant—a germ—acts in the tissues and causes the growing epithelium to be pushed down, and causes it to infiltrate into the tissues, while in the corn it is simply an accumulation of the epithelial cells on the surface. The ordinary corn or callus is an epithelioma in the true sense of the word, but time and usage have determined us not to call this an epithelioma. Now let us return to our smoker.

The pipe has irritated the crack or abrasion of the lip. The man is of a carcinomatous diathesis; just what a diathesis is we do not know, but he has the chemical condition within him which makes him a suitable soil to develop cancer. Such a condition is tuberculosis, that springs up from grief or exposure. Many thousand people smoke a pipe and do not get cancer, because they do not have the diathesis. As a result of the irritant, the cells proliferate and produce a chemical substance called a ptomaine. This increases the irritation on the inside and causes the proliferation to continue. The cells do not accumulate on the surface, but infiltrate into the subcutaneous tissue, muscles, and periosteum. These cells proliferate wherever the germs exist to irritate them. Remember, then, that in a corn the irritant comes from without, while in epithelioma the irritant is a germ which acts from within. So much for epithelioma, and this leaves out of consideration a whole class of tumors in which the process is identical, whether on the surface of the skin or beneath it. Laying this aside, let us consider that character of growths represented by fibrous tissue, which includes all fibroma, sarcoma, and scirrhous cancers.

The processes of Nature are blind, and she acts just as she is forced to act. When we have an amputation, the large flaps are open, and a dreadful gap has been made. The surgeon cleanses the wound, renders it aseptic, sews it up, and trusts to Nature to cure it. All the elements that are concerned in cancer are brought to bear here, and grow and heal the wound. The very elements that Nature puts in the most malignant cancer enter into the process of healing wounds. In a cut or wound, as a result, a clot forms in the mouths of the vessels and checks hæmorrhage. The blood is still being forced into the vessels, and in these vessels are small mouths or stomata against which a white blood cell fits. The cells enter the stomata and, by an hour-glass contraction, escape from the vessel as leucocytes, giving us the phenomenon of diapedesis. The leucocytes are destined by Nature to grow into fibrous tissue by their elongation. When millions of these leucocytes are exuded into the wound, we say it is covered with healthy granulations. These soon fill the wound, and it is found that those which fill the bottom of the wound have become fibrous; above this come the spindle-shaped, and on top the round cells. Finally, all that remains to complete the healing is to cover it with epithelium. If, for some reason, the leucocyte had not grown, but had been killed, it would have undergone fatty degeneration and given us a pus cell. You must retain these steps and follow them closely if you wish to get the least accurate notion of the development of cancer.

You will find nothing but fibrous and epithelial tissues in cancer, but they are arranged differently from the normal

tissues of the body. Sarcoma is a variety of fibroma. Just as epithelioma is a variety due to the growth of epithelial cells, fibroma is due to the growth of. fibrous cells. In fibroma there is an exudation of cells from a vessel which undergo the same change that they do in the healing of an ordinary wound. If you make sections of a fibroma and examine them with the microscope, you find cells of different ages representing the round, spindle, and fibrous cell, all in the same tumor. When you find the fibrous cells in excess, it is a fibroma; when the spindle cells predominate, it is a spindle-cell sarcoma; and if the round cells are in excess, it is a round-cell sarcoma. A fibroma and a sarcoma are really the same thing, but the sarcoma grows much more rapidly than the fibroma. A fibroma can not become a fibroma until it has undergone the same process of growth as a sarcoma.

True carcinoma develops either as the soft encephaloid or hard scirrhus in the glands. Just as we have the epithelioma on the surface, we may have a growth of endothelial cells in a gland, giving us the encephaloid (brain-like) cancer. When the mass is simply composed of endothelial cells with a very small amount of fibrous tissue and without structure, it is the encephaloid. A scirrhus is nothing else than a combination of an encephaloid and fibrous tissue in which the fibrous tissue predominates. It is much harder than the encephaloid, but the process of development is the same. The epithelial cells are inclosed with fibrous cells, forming alveoli.

We next come to consider the mucoid and amyloid cancers. Nature can do nothing more than I have stated, and these cells, growing under abnormal circumstances, die, and, being contracted upon by the fibrous tissue, undergo amyloid, mucoid, or calcareous degeneration, giving us these forms of cancer.

Metastasis.—To my mind, the very best proof of malignant growths being due to a micro-organism is the element of metastasis—that element by which a growth, if not properly removed, will break out anew in the same or another place, as only one germ is required to develop it. A tumor may be thoroughly removed, but, if a neighboring gland is affected, what can be plainer than that the poison has traveled along the lymphatics and developed? Here is an idea that I wish to submit to you that will take away any absolute or stereotyped rule, and that is when to pronounce a growth benign and when malignant. Why call the one growth benign and the other malignant?

The thickened epidermis on the hand is benign because the irritant that produced it was outside of the body and can be removed. The epithelioma is malignant because *it returns;* the irritant in the tissues has not been completely removed. There is one more growth, and that is the lipoma. A lipoma is nothing more than a fibroma in some of whose cells are deposited fat globules. The oil in the cell has simply pushed the nucleus to one side. A fibrous cell does not possess the power of infiltration like the epithelial, and is self-limiting and movable as a rule and benign. True cancer is immovable because it infiltrates.

Here is a man who had epithelioma of the penis that was removed a year ago, and now he comes back with a similar growth in his groin. What I wish to call your attention to is this fact: If you cut into this tumor and prepare microscopical slides from the different portions of the tumor and give them to a pathologist to examine, he will give this report: One section contains epithelial cells all over it, and he would pronounce it an encephaloid. If another section made from the thickened skin were given him, he would say epithelioma of a malignant type. If I cut still farther up he would say sarcoma; and if lower down he would say fibroma. This illustrates the great caution necessary in making a diagnosis. If the glands are involved it is a carcinoma. If the epithelial tissue is involved it is an epithelioma. All these types can be and are present in the same growth.

The nature of a cancer therefore depends upon the nature and arrangement of the cells in the particular section examined, remembering that the element of benignity or malignancy simply refers to whether the irritant which is the cause of the growth has been completely removed from the system or not.

Original Communications.

A CRITICISM OF WILLETT'S OPERATION FOR TALIPES CALCANEUS.*

By A. B. JUDSON, M. D.,
ORTHOPÆDIC SURGEON TO THE OUT-PATIENT DEPARTMENT OF THE NEW YORK HOSPITAL.

The object of Mr. Willett's † resection is to shorten the tendo Achillis and other fibrous structures at the back of the leg, the abnormal length of which produces talipes calcaneus with its characteristic elevation of the toe and depression and enlargement of the heel.

We are apt to speak of the *deformities* which are seen in orthopædic practice, but it would be more accurate in many cases to use the word disability instead of deformity. In talipes calcaneus, for instance, the deformity is not important. A large heel and a small anterior part of the foot do not make, in an ordinary case, a bad deformity. But the disability attending every case is very serious.

In the normal condition the action of the muscles enables the anterior part of the foot to support the body, and the result is an equable gait, the weight at each step coming first on the heel, and then, as the body presses forward, being transferred to the toe. But when the muscles are paralyzed the patient halts and is seriously crippled. He has the stumping gait which goes with a peg-leg. He can throw no weight on the anterior part of the foot, which might as well be absent so far as its usefulness in walking

* Read before the Orthopædic Section of the New York Academy of Medicine, March 21, 1890.

† Remarks upon Resection of the Tendo Achillis in Paralytic Talipes Calcaneus. Alfred Willett, F. R. C. S. St. Bartholomew's Hospital Report, 1880, pp. 307–310. Four Cases of Talipes Calcaneus of Paralytic Origin treated by Excision of a Portion of the Tendo Achillis. Mr. Walsham. *British Medical Journal*, June 14, 1884, pp. 1147, 1148.

is concerned. A similar disability was produced by the American aborigines, who amputated the anterior part of the foot (Lisfranc's operation) to prevent the escape of a captive without lessening his ability to labor.

Dr. Holmes, using the accompanying cut as an illustration (Fig. 1), analyzes the complex act of walking in these words: "Walking, then, is a perpetual falling with a per-

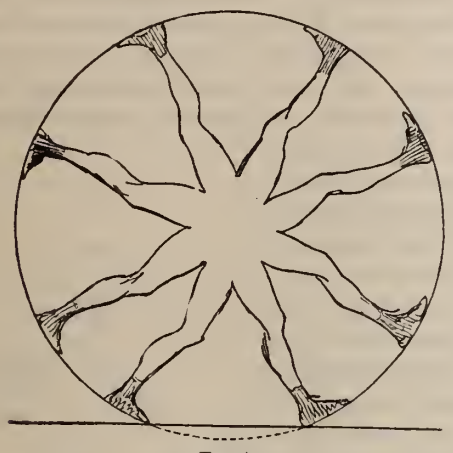

Fig. 1.

petual self-recovery. Man is a *wheel* with two spokes (his legs) and two fragments of a tire (his feet). He *rolls* successively on each of these fragments from the heel to the toe. If he had spokes enough he would go round and round as the boys do when they 'make a wheel' with their four limbs for its spokes. But, having only two available for ordinary locomotion, each of these has to be taken up as soon as it has been used and carried forward to be used again, and so on alternately with the pair." * Therefore, when a patient is disabled by paralytic talipes calcaneus, it may be said that some fragments are gone from the felloes of the human wheel.

The cause of the tendinous elongation in talipes calcaneus is obvious. At every step the foot is forcibly flexed on the leg without adequate muscular resistance at the heel, and the result is that the tendons become stretched and useless. In a normal limb the muscles at the back of the leg form a group of remarkable size and power, the principal function of which is to sustain the body when the foot is extended on the leg, and it is an interesting question whether the cicatricial tissue following a resection of the tendo Achillis is able to resist the weight which it is the function of this great muscular group to uphold. Extension of the foot on the leg while the limb is pendent or recumbent may be effected by the action of a few muscular fibers, but this function is of no importance compared with the power to hold the body on tip-toe, which can only be done by supreme muscular exertion.

In order to demonstrate clearly the severity of the strain which falls on the muscles of the calf and the tendo Achillis, I have made the machine shown in Figs. 2 and 3, in which wooden sticks represent the leg and the foot and a spring balance the tendo Achillis. The weight of the body is represented by a bag of shot weighing four pounds. The machine can be balanced in an upright position for an indefinite time by a light touch of the hand, and the joint representing the ankle is adjustable at any point between the heel and the toe. On trial of the machine the spring balance is seen to vary in its registry when the joint representing the ankle is moved to a new point between the heel and the toe. When it is near the toe the balance registers a small fraction of a pound, and when it is at a point near the heel the balance indicates twenty or twenty-four pounds, the limit of the scale.

In Fig. 2 the ankle is half way between the heel and toe, and the balance registers four pounds, showing that if the ankle in the human foot were midway between the heel and

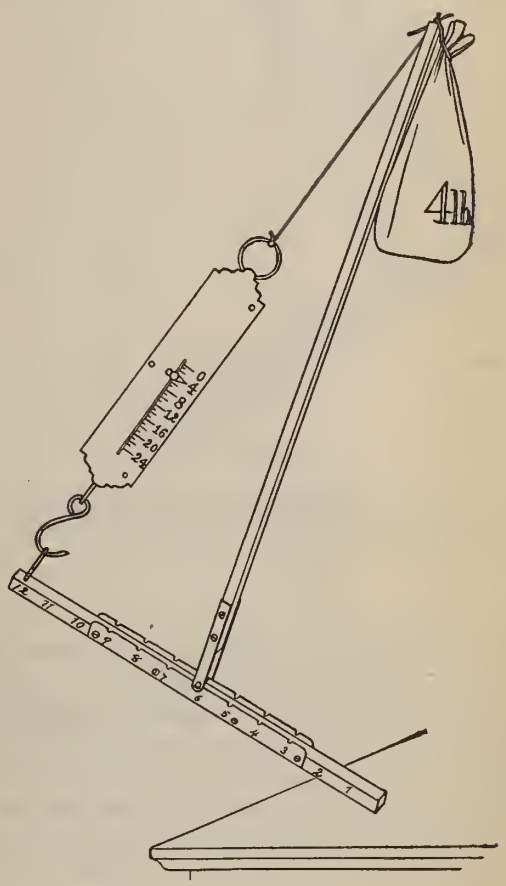

Fig. 2.

toe the strain on the heel-cord would equal the weight of the body. In Fig. 3 the machine is so adjusted that it measures three inches from the ankle to the heel and nine inches from the ankle to the toe, a proportion which approximates nature. It is now seen that the balance registers twelve pounds, or three times the weight of the bag of shot which represents the body. It is thus demonstrated that if a boy weighs one hundred pounds the strain on his tendo Achillis when he is balancing on tip-toe approximates three hundred pounds.

It is noteworthy that the strain decreases as the vertical line through the heel approaches the vertical drawn through the toe and the center of gravity and disappears when these lines coincide, as they do perhaps in the extreme poise of

* The Human Wheel; its Spokes and Felloes. By Oliver Wendell Holmes. *The Atlantic Monthly*, May, 1863, pp. 567–580. Cut used by permission of the publishers.

the ballet-dancer. But in the ordinary movements and in what is attempted by an operation it is impracticable to try to reduce the strain on the tendo Achillis by exaggerated extension of the foot on the leg.

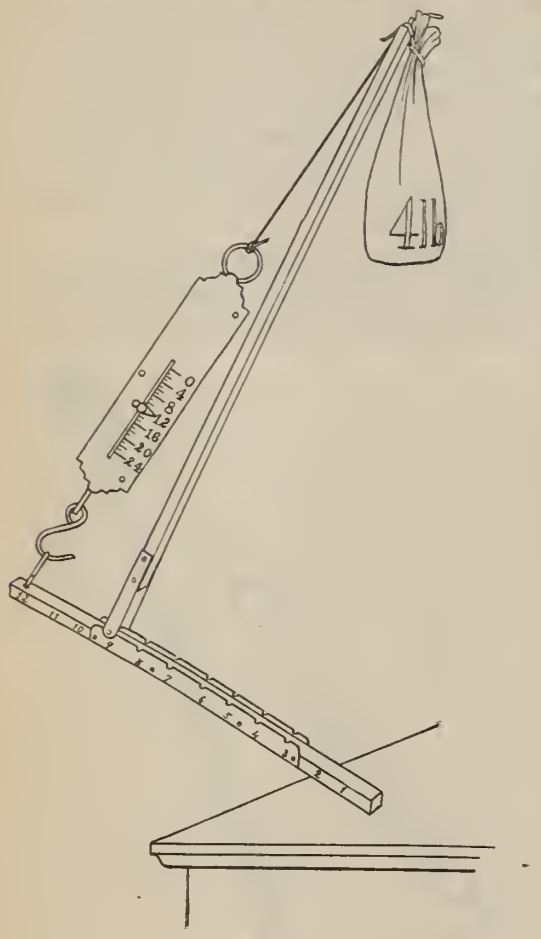

Fig. 3.

It is also noteworthy here that, if the gastrocnemius and soleus are paralyzed, it is impossible for the smaller muscles (the flexor longus pollicis, flexor longus digitorum, tibialis posticus, and the first and second peronei) to sustain unaided the weight of the body, not only from their small size, but also because they act at a peculiar disadvantage. The tendons of these muscles pass behind the malleoli to be inserted on the plantar surface of the foot, and their ability to sustain the weight of the body is to be estimated as though they were in fact inserted at the posterior borders of the malleoli. This insertion is evidently much nearer the point of motion at the ankle than the posterior extremity of the os calcis, as may be seen in Fig. 4, from Marshall's *Physiology*, although the space is doubtless exaggerated in this cut. The smaller muscles above mentioned, acting thus at a still greater mechanical disadvantage than the soleus and gastrocnemius, are more certain than they to be violently stretched when the weight of the body falls on the toe in the absence of adequate muscular contraction at the heel. The muscles in question are therefore very properly left out of our calculations.

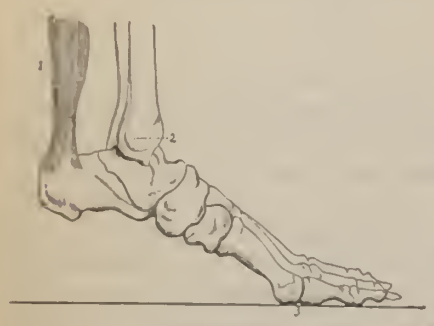

Fig. 4.*

That the tension falling on the heel cord greatly exceeds the corporal weight is thus seen to be a matter of physical demonstration. It is also found to be in accord with the formulæ of mechanics. It has long been recognized that the foot is a lever of the second order, as is shown in Fig. 4, the weight (2) being between the power (1) and the fulcrum (3).

Fig. 5 also shows a lever of the second order, the forces in equilibrium about the fulcrum C being the upward tension of the heel cord at A, represented by T, and the downward pressure of the tibia DB at B, represented by R. The moments being equal, $T \times AC = R \times BC$. As R is the resultant of the tension of the heel cord and the resistance of the ground at C, which is equal to the weight of the body, represented by W, $R = T + W$. Therefore $T \times AC = (T + W)\,BC$, or $T \times AC = T \times BC + W \times BC$, or $T \times AC - T \times BC = W \times BC$. But $AC - BC = AB$. Therefore $T \times AB = W \times BC$, or $T = \frac{W \times BC}{AB}$.

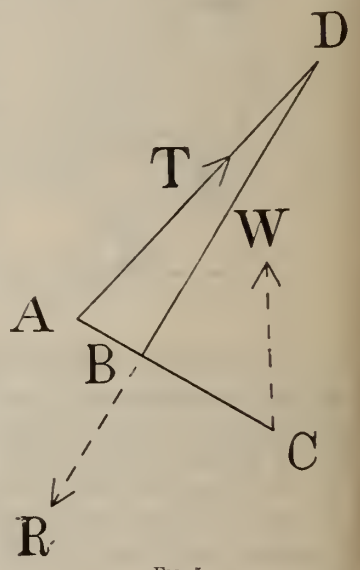

Fig. 5.

If, now, the weight of the body is one hundred and fifty pounds and the distance from the ankle to the toe, BC, is six inches, and the distance from the ankle to the heel, AB, is three inches (a fair statement of the proportion, which is probably greater than two to one and less than three to one), the tension on the heel cord is $\frac{150 \times 6}{3}$, or $\frac{900}{3}$, or three hundred pounds.

In this demonstration accuracy would require the forces to be considered in their perpendicular distance from the fulcrum, but practically the same result may be reached by the use of cosines, as in a valuable paper by Dr. William E. Wirt (*Medical Record*, June 28, 1890, p. 725). It is also to be borne in mind that the tension is even greater than is represented above, because in some of the more violent movements of the body the strain is the sum of weight plus momentum.

It thus becomes difficult to believe that the cicatricial tissue formed in the tendo Achillis after resection will be able to endure the test of use. It is not likely that the cicatrix is ever broken, because patients habitually guard

* *Outlines of Physiology.* By John Marshall. American Edition, 1868, p. 163, Fig. 49. Cut used by permission of the publisher.

such a point from undue violence; but there is certainly nothing to prevent the tendon from again becoming elongated. It was lengthened, in the first place, by the weight of the body repeatedly falling on the toe in the absence of adequate contraction in the muscles of the calf. Muscular power is still absent, and the tendon, exposed to the same strain, will again become elongated in the cicatrix or in the fibrous tissue above or below.

I do not remember having read any earlier exposition of the mechanical disadvantage which falls to the lot of the tendo Achillis and the muscles of the calf.* It is not probable that this important point has been entirely overlooked. But the question of prior recognition and appreciation of the adverse lever at the ankle joint is less important than to again call attention to a simple and not very expensive method of mitigating, by mechanical means, the disability which accompanies talipes calcaneus.

The brace in question supplies the place of the anterior part of the foot. It does in a simpler and perhaps more effective manner what has been done before by other forms of apparatus. Its object is to prevent the foot from being flexed on the leg when the weight of the body falls on the toe. A growing child thus affected should wear this simple apparatus, not only because the gait is thus immediately improved, but also persistently through the period of growth, because enlargement of the heel is thus prevented, and in after life the gait, without the brace, is much better than it would have been if the tendons and muscles of the calf had been over-extended at every step during the time of growth.

The brace restores to the patient the ability to stand on tip-toe, and to use the anterior part of the foot to sustain the weight of the body in ordinary locomotion, as well as in the more active movements of the body. Fig. 6 is copied from an instantaneous photograph dated 1885 of a patient, at that time a young girl, whose unaffected leg measured two inches and seven eighths more in circumference than the affected one. Without the brace she can not put the smallest fraction of her weight on the toe of the affected limb, but with the brace applied she balances herself on tip-toe with ease, as shown in the cut.

Fig. 6.

When I examined this patient recently, after an interval of several years, the (infantile) paralysis persisted, as was expected, but the deformity characteristic of talipes calcaneus was present in only a very moderate degree. She had worn the brace persistently with comfort and advantage. When she walks carefully, wearing the apparatus, her gait is free from the slightest defect. She sometimes lays it aside to please importunate but mistaken friends, but insists on wearing it when the duties of housekeeping are urgent, and will not appear out of doors without it.

This brace should be made without a joint at the ankle, differing in this respect from the one described in detail by me in 1885.* Experience has shown that the joint was useless, and the cause of frequent and expensive repairs. In some cases, also, the knee becomes slightly flexed, evidently because habitual flexion is necessary to enable the tibia to press against the padded strap at the upper part of the apparatus. It is therefore desirable to attach the upright near the posterior extremity of the foot piece, and also to incline it backward at an angle (in some cases 10°), which may be determined for each case by repeated trials. The angle may be changed, for experiment, by a heavy blow delivered in an anteroposterior direction while the upright is suitably supported at each end.

Fig. 7.

In other respects the brace, shown in its present condition in Fig. 7, is unchanged, and continues in use by a number of patients. It transfers the forces of weight and momentum, which in the normal foot are received at the ball of the toe, to the upper part of the anterior surface of the leg near the tubercle of the tibia, where a callus and an adventitious bursa are produced. Adults wear it constantly, as they would an artificial limb, with great increase of their ability to walk well and far.

In many cases the improvement in walking is partly due to an apparent increase in the length of the limb. The brace is easy to adjust, inexpensive, almost indestructible, and certain to add to the patient's comfort and ability. If necessary, webbing may be attached to prevent or lessen the valgous condition which often accompanies talipes calcaneus.

The Madison, East Twenty-fifth Street.

Hydracetin in Skin Diseases.—"As the result of some observations on the use of hydracetin in skin diseases, Dr. E. Basch finds himself unable to agree at all fully with the laudatory accounts which have been given of its action by some other observers. He finds that it is decidedly poisonous, even when applied externally. In a case of general psoriasis, where a ten-per-cent. ointment was applied to a third of the surface of the body, after ten days' treatment the skin and mucous membranes became quite pale, and, though the hydracetin was then stopped, hæmoglobinuria and jaundice supervened. The pulse became very rapid, but, notwithstanding the constitutional action of the drug, the psoriasis was not benefited. Dr. Basch finds that hydracetin, though a powerful reducing agent and useful in small patches and limited areas of psoriasis, has by no means the specific effect that pyrogallol and chrysarobin apparently have."—*British and Colonial Druggist.*

ON TWO CASES OF MUSCULAR DYSTROPHY.

By HENRY S. UPSON, M. D.,
PHYSICIAN TO THE LAKESIDE AND CITY HOSPITALS, CLEVELAND, OHIO.

The classification of diseases is a by no means unimportant subject in medicine, and, in our continued ignorance of final causes, is, in fact, almost the chief way of increasing the existing stock of medical knowledge. A perfect classification could only proceed from omniscience, and can not be hoped for. However, there are certain broad principles which should be kept in view in order to make an at least useful division of disease types; the most fundamental of these is never to generalize except from a large, in fact the largest possible, number of cases. It is true some new diseases have been described from a single case; but this is a rather dangerous precedent to follow. There is a limit to the value of dividing types of disease into groups and subgroups.

The dangers of over-classification are well shown in the somewhat protean disease-form known as muscular dystrophy. This affection, a few examples of which had before been described by an English observer—Meryan—was first clearly marked off from other trophic disturbances of the muscular system in 1861 by Duchenne, of Boulogne. His description was based on a study of thirteen cases, and was soon followed by the publication of several cases in Germany and England.

The name under which the disease has usually been described is the one proposed by Duchenne—pseudo-hypertrophic muscular paralysis. Subgroups soon began to appear as different forms of the affection came under the eye of various observers, and distinctions were made according as cases were affected early or late in life (juvenile form of Erb), or from the muscle groups which happened to be early affected (face and arm type of Landouzy, Déjérine, and others).

It has become evident that the disease may begin in an endless variety of ways, and there is a growing tendency at present to do away not only with all classification from a regional basis, but also all nomenclature which may be misleading as to the as yet unknown cause of the affection.

At one time the involvement of the facial muscles was a source of contention between the German and French observers. This feature of the disease, first described by Duchenne,* has been for some reason rare in Germany, although sufficiently common in France. It is shown in a quite marked degree in the following case, which has lately come under my observation:

A. J., a boy aged seven, parents both living and healthy. The patient, an only child, has always been rather delicate, but was considered moderately well until six months ago. Then it was noticed that there was a weakness of the neck. If the head fell forward it was rather difficult to get it back, and there was some bulging of the spine at the back of the neck. This is all that the patient complained of. About a month ago he had the measles, from which he made a good recovery.

On inspection, the patient is a frail-looking boy, with a very well developed head. The face, however, has a stupid expression, the upper lip being very thick and the mouth open the greater part of the time. The whole face has a rigid appearance, especially noticeable when the patient talks or laughs. It is quite impossible for him to pucker his lips to whistle or even to blow; this condition of things has become marked within the last few months.

The accompanying photograph shows very well the habitual expression of the patient, but fails, of course, to convey an adequate idea of the almost entire immobility of the face, which is the most striking feature of the case. The palpebral openings are equal; the pupils are equal and react to light; there is no apparent weakness of any of the ocular muscles, and no diplopia. The arms are both very small, the deltoids markedly atrophic, especially the right one, which has almost entirely disappeared. The arms can neither of them be

* *Paralysie musculaire pseudo-hypertrophique*, Paris, 1868, p. 19, Obs. xii.

raised above the horizontal. The scapulæ project, the inferior angles being thrown back, giving a markedly winged appearance when the patient stretches his arms in front of him. The cervical vertebræ show a marked curvature backward, due apparently to a wasting of the deep muscles of the neck and upper part of the back. The muscles of the lower part of the back seem strong and large enough. The head is carried well back, or, if allowed to go forward, drops on the chest. There is no lateral curvature of the spine, and no tenderness over any of the vertebræ. The abdomen protrudes somewhat. The thighs and legs are of good size; they do not seem at all hypertrophic, and are fairly strong.

The dynamometer registers a grasp of 4 with the right hand and 14 with the left. The muscles of the upper extremities react well to the faradaic current, except the right deltoid, which does not react at all. The reaction to the galvanic current is normal in the right forearm and left deltoid, KCC>AnCC, and the response on closure of the circuit is prompt and rapid. There are no triceps or wrist reflexes. The knee-jerks are slight, but are distinctly present. There is no anæsthesia. The patient gets up from the floor in a very peculiar way by pushing himself with his head, seemingly on account of weakness of the muscles about the shoulders, which prevents him from assisting himself with his arms. Once started, however, he raises his body quite easily by means of the muscles of the lower part of the back. This is quite different from the characteristic way which some patients have of raising themselves, so well figured by Gowers in his excellent monograph,* and which is rendered necessary by weakness of the muscles of the small of the back. There are a few moist râles over the lungs; the percussion note and breathing sounds are normal.

It is necessary to distinguish this case from the paralysis of Pott's disease, which it resembles somewhat on account of the curvature of the cervical vertebræ. A moment's consideration will convince us that the atrophy of the muscles is much greater in proportion to the loss of power than is ever the case in paralysis from pressure on the cord. In this connection the absence of the reaction of degeneration is also significant. This, with the absence of all sensory symptoms, pains, or anæsthesiæ, especially the absence of tenderness over the spine, the simple bulging of the vertebræ without deformity, and the positive symptom of involvement of the face, is ample evidence in excluding caries of the vertebræ as the cause of the trouble.

From muscular atrophy of spinal origin the diagnosis is not so easy, or would not be were it not for the involvement of the face. The absence of the reaction of degeneration is not so significant as would at first sight appear, since in the latter disease the process is so gradual, the affected muscles being attacked fiber by fiber, that in any given muscle there are enough healthy fibers to give the normal prompt reaction up to the time when the muscle has almost disappeared. Muscular atrophy of spinal type has, however, certain characteristics in its mode of development. It is apt to begin in adult life, attacking first the small hand muscles, which here are not affected; above all, the facial muscles, if they are involved, present the clinical picture of glosso-labio-laryngeal paralysis, or bulbar paralysis, which certainly is not present in this case.

* *Pseudo-hypertrophic Paralysis, a Clinical Lecture*, London, 1879.

As all evidence of disease of the spinal cord is wanting, we must refer the case to the class of muscular dystrophies, and, for lack of a better name, call the affection pseudo-hypertrophic muscular paralysis.

The next case has some similarity with the preceding one, but is unusual in developing side by side with another nervous affection as mysterious in its origin and ultimate pathology as is the one under consideration.

M. T., a bright, intelligent-looking girl of fifteen, was quite well until three years ago; then it was noticed that she was walking a little lame. This gradually increased, and a year ago she became unable to get her left heel to the ground. It was also noticed three years ago that there was a swelling of the throat, which has since become more marked. The patient has complained of shortness of breath, especially on going up stairs, but has had no palpitation of the heart. The appetite has been poor lately, the bowels regular. The patient is one of four children; the others are all healthy.

On examination, the eyes are somewhat protruding and wide open, but can be readily and completely closed. This protrusion has been noticed by the child's mother, and has increased of late. The pupils are equal and react to light, the color is good, and facial muscles normal in appearance and action. The tongue is protruded straight. There is a very well marked enlargement of both thyreoid glands. The pulse is soft and regular, and under the excitement of the examination 104. The heart sounds are normal; there is no murmur. There is a marked reddening of the skin where the clothing touches the body; if the nail is drawn across the skin, in a few moments a bright-red line appears and persists for some time. The arms, forearms, and deltoids are markedly atrophic, but the interossei, pectoral, abdominal, and back muscles are of fair size. There is no distinct paralysis of any of the muscles. All the movements of the arms can be carried out, but weakly. Grasp, according to dynamometer, 18 with right hand, 17 with left.

To the faradaic current all the muscles of the upper extremities react, except the extensors of the fingers; in these a reaction can be obtained only in the right extensor minimi digiti. To the galvanic current all the muscles of the upper extremities react promptly, and KCC>AnCC.

In the lower extremities all of the muscles seem moderately wasted, except those of the right calf. The latter is plump and

firm, in contrast to the left calf, which is small and flabby. When the patient stands the feet are held rather wide apart; the right heel can with some difficulty be brought to the ground;

the left foot is held in the position of talipes equinus; the heel can not be brought anywhere near the floor. The knee-jerks are absent on both sides. The muscles all of them act fairly well, although weakly; electrical reactions not tested. There is no protrusion of the abdomen. Sensibility is normal all over the body.

Ophthalmoscopic Examination.—Optic discs clear, of a rather pinkish color. Fundus of both eyes normal.

The diagnosis of exophthalmic goitre is obvious in this case, from the enlargement of the thyreoids, coincident protrusion of the eyeballs, the latter not yet sufficiently well marked to cause von Graefe's symptom, and the so-called "tache cérébrale," which in this affection is sufficiently common.

The tremor which is often in these cases very marked is replaced by another set of motor symptoms, sufficiently characteristic, and which, taken together, certainly deserve to be ranked as pseudo-hypertrophy. The weakness, the wasting of certain muscle groups are present, and with them another condition which is found in many of these cases, a contracture and shortening of the muscles, leading to club-foot and other deformities. The only distinctly hypertrophic muscles at present are those of the right calf, although other groups may have been enlarged earlier. Of this no history can be obtained.

It is almost useless to speculate on the probable connection between the two distinct affections from which this girl is suffering. Trophic and vascular disturbances are no doubt intimately related in their dependence on nerve supply, but too little is as yet known in this field to warrant any conclusions from such a case as the present one. The coincidence of two such affections is, however, somewhat suggestive.

A word may still be necessary, on the distinction of the above cases from those forms of disease which are marked by changes in the motor ganglion cells of the cord. That caution is necessary in postulating disease of the cord from a partial reaction of degeneration, even when it occurs together with total atrophy of the small hand muscles, is evident from the case so carefully examined by Schultze,* in which these symptoms were present and in which not only the central nerve tissues, but also the peripheral nerves, were practically normal. I believe that, even in cases which, unlike the two just described, present no muscular enlargements, we may easily go wrong in assuming an organic basis for the disease; and in these two cases the absence of decided evidence of a nerve lesion is given much positive value by the marked though not extensive hypertrophy of certain muscle groups.

The treatment of the latter case has as yet been directed to the vascular rather than the trophic disturbance. With the lapse of time an operation for the relief of the deformity may become advisable, but gives, unfortunately, no more than a prospect of temporary relief.

NOTE ON THE ACTION OF PYOCTANIN AS AN ANTISEPTIC.

By W. W. VAN ARSDALE, M. D.,
ATTENDING SURGEON, EASTERN DISPENSARY;
LECTURER ON SURGERY IN THE NEW YORK POLYCLINIC.

Among the antiseptic agents more recently introduced, pyoktanin, one of the aniline dyes recommended as a dressing for wounds by Stilling (1), of Strassburg, has appeared to me, during a brief clinical experience with it, to offer special advantages in the treatment of a certain class of surgical affections. I therefore believe it deserving of more general attention, and do not hesitate to recommend its further trial, notwithstanding the adverse criticisms which have appeared regarding it in the German medical press (2, 3, 6). I am indebted to Mr. F. A. Stohlmann, of this city, for first calling my attention to it, which he did in May of this year. Since then I have used it in about one hundred and fifty cases, representing various surgical conditions and occurring, for the most part, in dispensary practice. The cases in which it proved most beneficial were superficial wounds, ulcers, abrasions, excoriations, burns, and all kinds of granulating surfaces. With its action on mucous membranes I have little experience. Only one preparation was used—the violet pyoctanin of Merck—and it was always employed in an aqueous solution, one part by weight in a thousand, the solution generally being prepared fresh. The powder and the yellow preparation (auramine) were used in very few cases only. With this solution simple absorbent gauze was saturated, which was generally applied still moist to the surface to be dressed. In some cases the gauze was kept a day or two and applied dry. The dressing was next usually covered with a protective, hospital oiled paper being generally preferred, this manner of dressing having proved most satisfactory for use in this climate, and especially where there was reason to fear any retention. In other cases, however, as in fresh aseptic wounds, the protective

* *Ueber den mit Hypertrophie verbundenen progressiven Muskelschwund, und ähnliche Krankheitsformen*, Wiesbaden, 1886.

was left off with more advantage. The dressings were allowed to remain as applied for three days on the average. Large wounds were found to require more frequent change.

The forbidding appearance of the solution and the gauze did not meet with any protest or remonstrance on the part of the patients, contrary to my anticipations. On the contrary, after the first application, the patients, of their own accord, expressed themselves warmly in its favor, and in every instance requested to be dressed "with the blue dressing." It was this indorsement of its properties which led me to continue its use. The intense staining qualities of the substance, as evidenced on its contact with the hands and apparatus, lose some of their terrors when one learns how readily alcohol or tinct. saponis will remove such stains (4). This property appears to me to be a serious objection to the use of the powder. The gauze, however, may be impregnated in a glass dish and manipulated with forceps and scissors without inconvenience. In fact, the coloring properties appear to me to have the advantage of keeping the dressings unsoiled by unnecessary contact, as well as of affording a test as to the thorough action of the disinfectant.

Under the treatment above described, the surfaces of granulating wounds which had been exposed for some time to the air did remarkably well. Secretion of pus was frequently cut short as soon as the dressing was used. In most cases, however, some pus continued to appear in the central portions of the dressings, until they had been changed twice or three times. The granulations proper always appeared in good condition under the dressing. In no case did exuberant granulations spring up, and where such were present at the time of applying the dressing, they soon, after two or three changes, assumed a healthy appearance. The pyoctanin has a moderately astringent action on the granulations. But where the dressing is allowed to remain on for one week and the gauze becomes discolored by the action of the pus, the granulations appear as under other dressings.

The epithelium about the edges of the wound showed no undesirable conditions. In no case was any eczema observed about the wound, nor were any other symptoms of irritation or increased serous secretion from the wound observable. On the contrary, the dressings appeared to favor the rapid and healthy growth of the epithelium over the granulations, so that ulcers which had been a long time healing healed very much more rapidly under the dressing described. In this particular lies the main advantage of pyoctanin over other antiseptic dressings for this class of wounds; the moist dressings, with the exception, perhaps, of creoline, are more irritant to the wounds, while the powders retard the growth of the epithelium. Burns, too, showed very satisfactory results with pyoktanin dressings, and compared very favorably with those treated with frequent oily dressings.

Necrotic tissue remains uninfluenced by pyoktanin; it is not even readily stained. The secretions from the sound tissue surrounding the necrotic parts, however, being minimized by the pyoctanin, and the formation of pus prevented, the eliminating action of suppuration is much interfered with by this agent. Consequently the coming away of sloughs and the cleansing of necrotic ulcers is not hastened by pyoctanin, but is retarded in the same manner as by other antiseptics. For some cases, as after severe burns, this action is of course desirable; for smaller sloughs, where rapid healing is desired, other dressings are more advantageous. It may be stated, however, that since the action of the pyoctanin, applied as above, does not penetrate through the slough, the elimination of the necrotic portion from beneath the slough in infected wounds is not essentially interfered with, so that, while eliminative suppuration goes on beneath the slough, the formation of epithelium goes on about the edges of the necrosed portion where the agent has access, so that ulcers so treated actually begin to heal before they are completely cleansed.

The action of pyoctanin on fresh wounds is very much the same as that of other antiseptics; they retain their normal conditions, and heal by primary intention. If the nature of the solution permitted of a less apprehensive use of the stain as an irrigating fluid, I do not doubt but that it would prove much more extensively useful. But as yet I am at a loss to see how the solution can become popular for such purposes.

Venereal ulcers were beneficially influenced by application of the dry gauze; secretion was diminished and formation of epithelium hastened. Syphilitic (tertiary) ulcers appear less influenced. The lengthy time of cleansing, the appearance of the slough, and the pain accompanying syphilitic ulcerations, are the same as under other dressing. Compared with iodoform, the latter appear to me to do better under iodoform, while the venereal ulcers (chancroids) do much better under pyoctanin.

In no case coming under my observation has there been any acute infection of a wound under a pyoctanin dressing; erysipelas, phlegmons, lymphangeitis, lymphadenitis, septicæmia, and pyæmia were not once observed as secondary affections after application of the dressings. But I am far from attaching much importance to this observation in consideration of the small number of cases seen.

In conclusion, I may say that pyoctanin appears to me to kill certain kinds of pus wherever it comes wholly in contact with it, but it has not the power to penetrate sloughs, and, where septic necrotic processes are going on, frequent change of dressings is necessary. It is non-irritant to wounds, and keeps granulations in good condition. It also insures the patient's remaining remarkably free from pain and subjective inconvenience. But, where the pain is deep-seated, or due to other conditions than those of the superficial wound, this effect of pyoctanin is not observed, as in the following case:

A robust man was driving a cart in a Brooklyn park, when his horse became unmanageable and kicked him, as he sat on the front of the cart, three times successively on the leg. Seen soon after by me, he presented a longitudinal wound of about four inches in length immediately below the tuberosity of the tibia. The edges were contused; at the bottom the bone was laid bare, denuded of its periosteum. Dressing with pyoctanin, the wound being first cleansed with pure water (all other disinfectants being avoided) and swabbed with moist pyoktanin gauze; coaptation sutures were applied, cocaine being employed hypodermically (Dr. Whitaker). The wound consequently did

well and presented an aseptic course, the contused edges of the wound becoming necrosed. But for the two days following the accident the patient suffered severe pain at the seat of the injury.

I may add that pyoctanin has been made the subject of careful bacteriological investigation by Jaenicke (6). Stilling and Wortmann, who tested the action of the dye on putrefactive bacteria, found (5) that it killed them in a concentration of 1 in 4,000, which Jaenicke confirms. But the latter author tested its action on pure cultures of several kinds of pyogenic micro-organisms. In bouillon *Staphylococcus pyogenes aureus* was killed by the addition of sufficient pyoktanin to represent a solution of 1 in 2,000,000. The streptococcus was killed by 1 in 250,000, and a diplococcus resembling the pneumonia coccus by 1 in 1,000,000. In blood serum the action was less pronounced, the staphylococcus being killed by 1 in 500,000 only. A 1-in-1,000 solution killed the *Staphylococcus aureus* in one minute and the streptococcus in five minutes, anthrax bacilli without spores being killed in two minutes and a half, while the bacilli of typhoid fever were not killed in fifty hours. In a dried condition the staphylococcus was killed by a 1-in-1,000 solution in five minutes, but when suspended in blood serum the same micro-organism was only killed after an hour's exposure.

From these data Jaenicke argues that the drug might be good as an inhibitory agent (to sepsis), but not as a disinfectant, where it would necessarily have to act in albuminous media.

Its toxic properties were also estimated by the same author. Mice survived the subcutaneous injection of one fifty-thousandth part of their weight of pyoctanin, while the intra-abdominal injection of a fourth of this quantity killed them.

Its non-coagulative effect on albumin has been recently pointed out by Stilling (7), so that in this particular it has the advantage over plain sublimate solutions.

A New and Rapid Test for Sugar.—"At a meeting of the Austrian Surgical Society last week, Professor Nothnagel showed a handy test for sugar, which had been forwarded to him by Dr. Becker, of Cairo. It is simply a visiting card saturated with a solution of potash, over part of which is drawn a covering of the sulphate of copper, and the urine applied. The card is then laid on the globe of a lamp, when the saccharine urine will color the card brown, and this color will be the deeper the greater the amount of sugar."—*British and Colonial Druggist.*

SOME POINTS IN THE EXAMINATION OF PERSONS FOR LIFE INSURANCE.

By C. L. DODGE, M. D.,
Kingston, N. Y.

Examination for life insurance requires special aptitude for this particular work. "To one who is thrown much with medical examiners it will be seen at once that they do not, as a rule, fully comprehend the position which they are called to fill" (Keating). A patient calling upon his physician is full of complaints, anxious to acknowledge all the pains and symptoms of disease he may be suffering from, and ready to communicate the cause and history of his malady; no information is withheld, and no questions are evaded. Not so in the examination of a risk for life insurance.

By the time a man has made up his mind to insure he has learned that a medical examination has to be passed. This the average man dreads, whether he is willing to admit the fact or not, for different reasons. A considerable experience in the examination of candidates for various lodges where sick and death benefits are paid, as well as for life insurance proper, warrants the correctness of this statement. First, many men fear that a rigid examination will disclose some hidden disease, or tendency thereto, which they would prefer to remain in ignorance of until they discover it for themselves. Others realize that rejection by one company will operate against them unfavorably if application should be made to another. Hence the dread of rejection.

For these reasons, we always note the absence of frankness so characteristic of ordinary patients.

No voluntary statements are made which would give color to poor health, past or present. Symptoms and ailments of both the applicant himself and of his family connections are made light of and undervalued. In the family history it is quite frequently observed that the applicant will intrench himself behind the negative information conveyed by the answer, "I don't know," to questions of vital importance to the examiner and the company. Many times these questions would be answered quite explicitly if the party was allowed or requested to call again with the desired information.

Medical examiners are frequently appointed by some of our largest companies arbitrarily, and with very little regard to fitness or qualifications. If a man stands well socially, or happens to be a personal friend of the agent, local or general, he is forthwith appointed the medical examiner. It is true that the company requires him to fill out a blank, furnished for this purpose, giving the college he graduated from, with date, etc.; but what does all this amount to in the way of showing a man's qualifications as a scientific physician? I will venture the assertion that not one physician in ten has a work devoted to the subject "examinations for life insurance" other than the little book of directions furnished by some companies. Ten years ago microscopy and

physical diagnosis * were not taught at any of our medical colleges except as special courses, which were taken by less than ten per cent. of medical students. How, then, I ask, is it expected on the part of the companies, with their haphazard way of appointment, that they will be able to secure first-class men to act as their medical examiners in the smaller cities and country towns? The medical officer at the home office is supposed to pass finally on all applications received. Inability of the applicant to reach a certain arbitrary standard is sufficient to bar him out; but the medical director, in my opinion, is very much in the same position as the alleged specialist who guarantees to make a positive diagnosis from answers to a set of printed questions. Any well-educated physician knows the fallacy of such a procedure. If a man's family history is bad, if his own health is below par, or if he has ever suffered from a disease which experience has shown to be frequently followed by dangerous sequelæ, why, the merest tyro in medicine would reject him, and the home office would simply have to indorse the rejection.

But all cases are not so easily disposed of. Certain individual peculiarities are sometimes met with, such as an abnormally frequent or slow pulse, with regard to which some companies are exceedingly strict. An unusually fast or slow pulse *per se* should not cause the rejection of an otherwise healthy man.

From time immemorial morbid characters of the arterial pulse have been ranked among the most important of objective symptoms. The pulse is a valuable aid to diagnosis, but it is sometimes misunderstood and misinterpreted. Many healthy persons are so constituted that nervousness or, more correctly, excitement, as the result of an examination, will cause an increase of fifteen or twenty beats a minute.

Tact on the part of the physician, by leaving this part of the examination to the last or counting the pulse the next day, will often make a vast difference.

Strange to say, the thermometer is rarely made use of by medical examiners; if there is a suspicion of fever, as in the so-called pretubercular stage, the temperature is of much greater importance than the pulse. A slightly frequent pulse, with no evidence of disease of the heart, lungs, or kidneys, has no pathological significance. The same may be said of functional slow pulse, within certain limits. A pulse below sixty-five is generally regarded as abnormal.

It has been said that longevity depends far less on race, climate, profession, mode of life, or food, than on hereditary transmission. This is a sweeping assertion and should not be made unqualifiedly. That tendencies or proclivities to certain diseases exist no one will deny; but, with the exception of phthisis, epilepsy, cancer, rheumatism, and gout in its fullest sense, we do not see the effects of hereditary influence so markedly in this country as they are observed in Europe, where generation after generation live under the same roof, drink the same water, eat the same food, and follow the same occupation. In this country people are continually changing their residence, their occupation, and, as circumstances will permit, their mode of life. If they lived the same life that their parents and grandparents did, they would be surrounded by the same influences, and doubtless would be subject to the same diseases to a certain extent. Some diseases seem to be endemic in certain localities. We all know how rheumatism prevails in one place, malarial fevers in another, and lung diseases in a third. These things are all to be taken into account in estimating hereditary tendencies.*

Not one man in a hundred will admit ever having had syphilis or stricture, although many will own up to gonorrhœa as an indiscretion of youth. Personal knowledge is sometimes of advantage in these cases.

No subject presents greater difficulties to a conscientious physician, however, than the use of alcoholic stimulants. Where is the line to be drawn between moderate drinking and over indulgence? In some cases there is absolute frankness; a man will say, "I take two drinks of whisky or two glasses of beer a day." More often, however, he will place the amount far below what is actually taken. Obviously, in these cases the home office is compelled to rely upon the honor and sagacity of their medical examiner, and he has to judge by the applicant's general appearance and previous habits in this regard. It is stated by Keating that, in spite of prevalent belief, consumption, cancer, apoplexy, paralysis, and disease of the kidneys show increase of mortality with advance of years, being greatest after fifty and sixty. This unqualified assertion is very misleading as applied to consumption. All authorities agree that phthisis is peculiarly a disease of young adults and early middle life. One has only to draw upon his own experience to corroborate this. Of 1,531 deaths between sixty and seventy reported to the New York State Board of Health for the year 1887, but 123 were from consumption.

If insurance companies generally would use one half of the care in selecting their local medical examiners that they do in preparing their examination blanks, and, after appointing an honorable, conscientious, scientific physician as their local examiner, would rely upon his judgment—subject, of course, to the rules and regulations of each particular company—in all doubtful cases, there would be fewer death losses to pay. Some examiners like to put the responsibility on the home office in these cases, but this is unfair to both the applicant and the company.

That accomplished author and physician, Oliver Wendell Holmes, says that "a diagnosis which maps out the physical condition ever so accurately is, in a large proportion of cases, of less consequence than the opinion of a sensible man of experience, founded on the history of the disease." We should be careful neither to overestimate nor to undervalue the information obtained by physical exploration, and in giving our final opinion we should strive to be just to the applicant and honorable to the company.

* Perhaps I should modify this statement slightly as to physical diagnosis. Didactic lectures were given on this subject in my student days, but the practical courses as now understood were special and extra. As to microscopy, it needs no qualification.

* Statistics collected in Europe with reference to the hereditary transmission of disease should never be considered as equal in value to those of this country, for the reasons set forth above.

ON STOMATITIS GANGRÆNOSA,

WITH SPECIAL REFERENCE TO ITS TREATMENT WITH LIQUOR FERRI SUBSULPHATIS.*

By J. D. SULLIVAN, M. D.,
BROOKLYN.

The majority of diseases of the mouth in children are attended by little danger and respond very readily to treatment, but the disease to which I desire to direct your attention in this paper is one of the most fatal affections of early life if allowed to take its usual course, unchecked by treatment; and yet it is quite easily curable if recognized early and the proper treatment is promptly applied.

Fortunately, the disease is exceedingly rare in private practice, but is quite frequently met with in public institutions where large numbers of children are housed together. It is described by different writers under various names, as cancrum oris, noma, necrosis infantilis, gangrene of the mouth, buccal anthrax, aqueous cancer of infants, scorbutic cancer, and sloughing phagedæna of the mouth. The disease appears to be more frequent in Europe than in the United States.

Many elaborate essays have been written on the subject by English, French, and German physicians, but outside the medical text-books there has been comparatively little written in this country. The only article which has come to my notice through our medical journals is a paper by Dr. Constantine J. Macguire, of New York, read before the Yorkville Medical Association and published in the *Medical Record* of February 3, 1883. The disease is limited almost exclusively to childhood, occurring most frequently in children of from two to six years of age, and with diminishing frequency to the twelfth and thirteenth years. It generally attacks children who are in delicate health or those who are debilitated by other diseases, especially measles, whooping-cough, and pneumonia.

The majority of authors maintain that the disease is not contagious, but my experience leads me to believe that it is certainly infectious if not contagious. The beginning of the disease is usually manifested by an extremely offensive odor to the breath, with a tense tumefaction of one cheek or lip, and a pale and glistening appearance of the skin. There is but slight elevation of temperature—about 101° F. The pulse is soft and feeble. The expression is melancholy and the patient is indifferent to surrounding circumstances. On examining the mouth, a small, black, dry eschar, circular or oval in shape, will be found on the buccal surface opposite the most prominent portion of the swelling, whether it be on the cheek or lip. If not checked by treatment, this swelling gradually increases in circumference, sometimes in a few days; at other times more slowly, taking in the entire side of the face or even extending down into the neck. The internal eschar extends equally with the external swelling, and eventually it becomes more or less detached, leaving a hole in the cheek, and the adjacent tissues change as the gangrenous process advances.

In other cases the disease begins on the alveolar border of the gums, frequently at the seat of a decayed tooth, and as it advances the gums become swollen, soft, and livid; the teeth loosen and fall out; and as the gangrene progresses, the maxillary bones become involved in the necrotic process. Although the suffering is not proportionate to the gravity of the disease, and liquid nourishment can be taken very well, prostration becomes more and more profound and the appearance of the child is melancholy in the extreme.

The peculiar gangrenous odor from the mouth is present in every case, and as the disease advances the fœtor becomes extremely offensive. A microscopical examination of the gangrenous tissue shows that it contains large colonies of bacteria which appear to be infiltrated all through the diseased portions.

In the cases which came under my observation overcrowding or insufficient ventilation appeared to be the chief factor in the causation of the disease.

With this brief sketch relating to the character of this distressing affection, we will now consider its treatment, which is my principal motive in calling your attention to this subject.

Both local and constitutional treatment are urgently demanded. Stimulants, tonics, and the most easily digested food should be given as liberally as the patient will bear. An abundant supply of fresh air is absolutely necessary to the proper management of these cases. Although this point is not even mentioned in many of the text-books, it is very essential that the entire premises should be thoroughly ventilated. Local treatment is of paramount importance, and alone is capable of arresting the progress of the disease. Many authors recommend energetic cauterization with the most powerful agents—nitric acid, hydrochloric acid, carbolic acid, nitrate of mercury, and even the actual cautery. From my experience, I can not approve of the topical application of such strong caustics.

In the paper heretofore referred to, Dr. C. J. Macguire reported twenty-four cases of cancrum oris, the first four of which were treated in accordance with the orthodox methods laid down in the text-books, and still the gangrene continued to extend until finally the patients died. When his fifth case appeared he was in despair, and concluded "that following in the old rut of treatment was almost useless, if not quite so." He then conceived the idea of applying locally the subnitrate of bismuth. After thoroughly cleansing the mouth with a disinfectant solution, he covered the ulcerated surface with the bismuth, and the next day the progress of the disease appeared to be arrested and the symptoms were much improved. He then had the mouth washed with a solution of carbolic acid and the bismuth applied every three hours. With this treatment and the administration of the syrup of the iodide of iron, cod-liver oil, and a generous diet, his little patient was cured in less than two weeks. After witnessing the happy change effected by the bismuth he pursued a similar course of treatment in his following nineteen cases, and, although some of these seemed to be almost hopeless in the beginning, they all recovered. It is evident, from the accurate description given by Dr. Macguire of his cases, that he was dealing with genuine cases of stomatitis gangrænosa, and that he instituted a

* Read before the Kings County Medical Association, May 9, 1890.

course of treatment that proved remarkably efficacious under his direction.

In one of the largest orphan asylums in this city, to which I have been the medical attendant during the last twenty years, we have had about thirty-five cases of stomatitis gangrænosa. Of these patients, two died from the effects of the disease; the remainder recovered. Of the latter, two lost a portion of the lower jaw bone from necrosis caused by the gangrene, but there is no apparent deformity as the result.

My experience with the disease began in 1878, when a boy who had just recovered from measles contracted scarlet fever, and during convalescence from the latter disease was attacked by gangrene of the mouth. He was treated according to the usual method, but a portion of one cheek was destroyed before the disease was arrested. After a great deal of care and constant attention, during a period of about three months, he was restored to health, with but little deformity.

In September, 1884, Eddie S. was admitted. He was about three years of age and in very poor physical condition, and shortly after he developed gangrenous stomatitis. Notwithstanding the most vigorous and diligent treatment the gangrene continued to extend until one entire side of his face and a portion of his tongue sloughed away. In this most deplorable condition he lived for about two weeks, during a portion of which time it was necessary to carry his food into the pharynx with a tube or spoon to enable him to swallow it.

During the year 1888 we had seventeen cases of cancrum oris. Many of these followed an epidemic of whooping-cough. Of these, sixteen patients recovered and one died. Many remedies were tried during the progress of these cases—subnitrate of bismuth, naphthalin, hydronaphthol, salol, listerine, permanganate of potassium, tincture of iodine, and various disinfectant solutions at different times, and still recovery was very slow, extending over periods of from one to three months.

The application of naphthalin gave as good satisfaction as any other agent used, if not better.

During the year 1889 six cases came under my observation. All the patients recovered more rapidly. It was during the progress of these cases that I conceived the idea of applying liq. ferri subsulphatis, diluted with an equal part of glycerin, and the result was much more satisfactory than with any remedy heretofore used.

On the evening of April 1st of this year, while hastily making my usual visit through the infirmary, my attention was called to a boy about six years of age with a swollen face and a most horribly fœtid odor to his breath. On examining his mouth, I found the gums of a dark-purple color, soft, pulpy, and very much swollen, and the teeth loosened. I instantly recognized the same old enemy which had given us so much trouble in former years. A moment's reflection satisfied me that the proper thing to do was to remove the dead tissue and endeavor to arrest the gangrene. Grasping the gums between my forefinger and thumb, and pressing upon them, I found that the dead parts easily separated from the living tissue. In this way I removed the greater portion of the gums on both sides, with several of the teeth. Then, with a large camel's hair brush, I copiously applied a mixture of equal parts of liq. ferri subsulphatis and glycerin. This arrested the slight hæmorrhage and contracted the remaining diseased portions into firm shreds. Now, with pledgets of absorbent cotton held in the grasp of a forceps, I cleaned out the mouth and made another application of the iron solution. This was all done in a few moments, with very little pain to the patient and with but slight resistance on his part. The next day the boy presented a much brighter appearance, and the disease had evidently made no further progress. Apprehending that the gangrene might still be lurking where it was so active on the previous day, I gently curetted the alveolar processes and tooth sockets, removing all the diseased tissue, and washed out the mouth with a solution of sulphate of copper, half a drachm to the ounce of water, and then thoroughly applied the solution of iron and glycerin. I then gave instructions to have this repeated four times daily. On the following day the parts presented a healthy, granulating appearance, and there was but very little of the offensive odor remaining. The applications were continued for eight or ten days, and at the end of two weeks the parts were healed over and the boy was in good health minus his molar teeth.

Within the next nine days five more cases of cancrum oris were developed in boys whose ages ranged from three to six years. These were all treated in the same way as the last case, excepting that two, which were seen in the incipient stage, were not curetted. In these two cases the mouths were simply washed with the solution of sulphate of copper, and the iron mixture applied as in the other cases. In each case the gangrene was arrested within three days after the first application, and their recovery was complete within two weeks. Whisky and good nourishment were diligently administered to every case, and ample ventilation was provided for them.

In carefully considering the action of the many remedies which I have used in the treatment of this destructive disease, I am satisfied that, so far as my observation extends, the solution of the subsulphate of iron is the most efficacious. Diluted with an equal part of glycerin, it appears to combine with the diseased tissue, and either dissolves it or converts it into an inert, odorless substance, without irritating the healthy parts. It is powerfully destructive to organisms of a low vitality, therefore serving as a good germicide and antiseptic, and consequently we might infer that it would be a valuable agent in arresting a septic disease like gangrene. Even after the eschar has been dissolved or removed by the application of this solution, it appears to promote a healthy granulation of the parts, and hastens their restoration to a sound condition.

If time would permit, I might extend these remarks by reciting the details of each case more minutely, but it would simply be a repetition of what I have endeavored to picture to your minds, and would be unnecessary, as this paper has been hastily prepared with the special purpose of bringing before the profession the treatment of this affection by the removal of the diseased portions, and the topical application of the solution of the subsulphate of iron diluted with an equal part of glycerin.

If others try it and obtain the same results that have attended my experience, many innocent children will be saved from a revolting deformity or death, and my efforts will be richly rewarded.

A VAPORIZER, SUBLIMER, AND AIR-STERILIZER.

By HERBERT F. WILLIAMS, M. D.,
BROOKLYN.

I deem the following propositions to be common ground of belief:

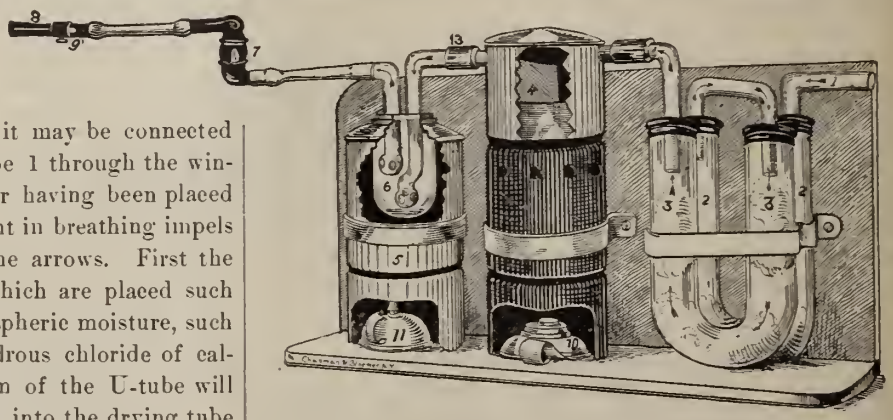
1. The respiratory avenues are influenced by various atmospheric conditions.

2. Systemic infection can be produced by the inhalation of germs or their spores.

3. Various gases and vapors are readily absorbed by pulmonary tissue.

4. The pulmonary tissue is capable of response to natural methods of autagonism to agencies which seek its disintegration.

5. Artificial means to produce Nature's methods must imitate her. In these propositions are the conception, birth, and elaboration of the instrument I now describe.



1, tube to connect with ontside air; 2, 2 and 3, 3, U-tubes for holding drying agents; 4, diaphragm in hot-air drum to compel a free circulation of the air; 5, drum to hold vaporizing glass; 6, vaporizing glass; 7, gravity valve, unscrewing at center, with valve inside; 8, mouth-piece; 9, opening in mouthpiece with adjustable cover to regulate expiratory force; 10, lamp for sterilizing drum; 11, lamp for vaporizing drum; 12 and 13, connections.

The cut shows the vaporizer on its permanent shelf, which is sixteen inches long and ten inches high. It shows the vaporizer adapted to the left window casing, where it may be connected with the outside air by extending tube 1 through the window sash. With it thus arranged, or having been placed upon a suitable stand or table, a patient in breathing impels the air in the direction shown by the arrows. First the air enters the drying tube 2, 2, in which are placed such agents as have great affinity for atmospheric moisture, such as pentoxide of phosphorus or anhydrous chloride of calcium (absorbent cotton in either arm of the U-tube will arrest all optical impurities); passing into the drying tube 3, 3, the air may be made more dry, and any chemical impurity of the lime or the acid can be neutralized by making it pass through broken sticks of caustic soda. It now passes into the hot-air drum, in which it receives a sterilizing temperature, which, of course, expands it; from the hot-air drum it passes in divided currents into the vaporizing glass, in which may be placed the agent that may be deemed of service in any special case; passing over this, the air enters directly into the respiratory current through the breathing tube.

The mechanism, then, is briefly this: Air strained and dried, sterilized and expanded, is submitted to agents from which it will resaturate itself according to natural law. Air thus holding its full complement of moisture for these conditions in the form of gas becomes the respiratory medium.

The changes in density of intrapulmonary air, made by forcible expiratory effort, can be theoretically shown to be sufficiently great to recondense saturated intrapulmonary air. This can not be shown practically, but the inevitable mechanical effect is to make the saturated air impinge against its surroundings, causing it to permeate unused areas, and thereby utilizing well-recognized forms of pulmonary gymnastics. Such a device seems to me to be an imitation of Nature's way in preparing volatile products (for she uses no other) for rendering air serviceable for diseased conditions; and, after over two years of experience with its principles, I am convinced that whatever of good can be gained by voluntary inhalation can be afforded by its use, and my constant and increasing experience teaches me that this good may be not a little. The fault with our management of phthisis, other than climatic (which to the masses is denied), is that radical treatment is not instituted at once.

It will not do for one to admit that a catarrhal bronchitis can be inoculated into a tubercular process, and deny the value of antiseptic air to prevent such inoculation, if coinstantaneously employed, and if the focus of absorption is in a remote portion of the body. What more conservative and honest effort can be made than to secure, by the best means, a continuous asepticism of the lungs? There is a theoretical instant of septic absorption. To discover it may be impossible; to expect and guard against it is our bounden duty.

Nutrition, begotten of healthy appetite and digestion, furnishes a barrier of germicidal blood serum. Should this be regarded as of more importance than anything else, let it be remembered that it is only one of Nature's ways of protection, and that it certainly does not interfere with other necessary precautions.

There are fourteen hundred and forty minutes in each day, and any means, however potent for good, which can be brought to bear but a small fraction of this time is applied at a great disadvantage. Such is a practical difficulty with the pneumatic cabinet, with which initial energy can be developed in the air cell, and a thoroughness of intrapulmonary medication absolutely impossible by any other known means. Vicissitudes in the weather, even in a climate fortunately adapted to a given case, are such that a serious interruption in a progress toward health can be made. I have endeavored to make this instrument a practical and comprehensive means for home use, where nothing but the judgment of the physician or the indifference of the patient can prevent its frequent, and, if necessary, prolonged application.

My patients easily understand its principles and experience no difficulty in its operation, and this has been the experience of a number of personal professional friends who have used it in their practice.

Indications for its application can be inferred from what has been said; and I bespeak for its clinical work only such accomplishment as is made possible by therapeutic acumen and the judgment which shall direct its use in acute and chronic conditions.

As represented in the cut, it may be used simply as an air drier and sterilizer, for the delivery of warm or cold air, or with such agents as benzoic acid, camphor, calomel, etc., it may be used as a sublimer. Experiments with hot air *per se* began over three years ago; first, by slaking lime in a convenient apparatus for delivery to the patient's mouth. Then a central attachment was made to the present instrument, which would deliver air at nearly 400° F.; but the relative proportions of the instrument now shown are such that the maximum temperature of the air for the vaporizing glass is about 212° F., and in its transit through the breathing tube it becomes lowered to within a few degrees above the temperature of the mouth. A higher temperature can be gained by using lamp 11 in connection with lamp 10, and for aqueous solutions or for sublimation it will be necessary to use it.

The degree of air saturation with more pungent agents can at all times be regulated to the point of toleration by adjusting the flames of one or both lamps.

An increased scope for the principles here shown can be gained by multiplying the drying tubes and allowing compressed air from a condenser to flow through an intermediate elastic air chamber, so as to avoid interference with the gravity-valve, 7; moreover, such a device is necessary to assist in the increased inspiratory effort thereby produced. Air under such conditions will resaturate itself to the degree of toleration with little or no heat. Such a device I use in my office in connection with the pneumatic cabinet, and nothing, excepting the increased expense, need prevent its general domestic use; but the instrument here shown has proved itself of great clinical value, and, I think, must be regarded as an advance in the field already occupied by kindred devices.

From the encouragement I have thus far received from professional friends, I judge it may possibly find a more general use. In anticipation of this rather presumptuous forecast, I wish to forestall any accusation of egotism, and at the same time satisfy truth and parentage and certainly euphony, by giving it that portion of my name at once historical—viz., Franklin. Such manipulation of the air as I have here described can not require any further explanation, and any suggestion with reference to the use of agents seems superfluous; still it may save some little trouble if I mention the agents I have thus far used, and this I will do. I am quite sure that some new questions will arise if inquiry is pushed in the direction of the hydrocarbon series, especially the aldehydes, ethyls, and methyls.

Ten drops of the following agents or combination of any of them is the ordinary dose employed: Tincture of camphor, tincture of iodine, creasote, carbolic acid, eucalyptus oil, Sylvester oil, terebene, benzoic ether, salicylic ether, paraldehyde, balsams, guaiacol, volatile oils, alcohol, chloroform, etc.

I beg herewith to acknowledge valued assistance in the mechanical construction from my friend and patient Mr. Walter C. Harlow.

THE LOCAL TREATMENT OF DIPHTHERIA AND SCARLET-FEVER THROAT.

By W. CHEATHAM, M. D.,
LOUISVILLE, KY.

I have lately had much experience with the treatment of these affections, and have found that hydrogen peroxide, fifteen volumes strength, alone or combined with bichloride of mercury, gr. j to ℥ j, gives me better satisfaction than any other remedy. Hydrogen peroxide is a thorough antiseptic, besides acting mechanically in getting rid of the membrane; it does the latter in the later or most dangerous stage, for it is at this time that septic infection is more liable to occur. When the membrane begins to slough, the peroxide will, when applied with a mop or in spray or as a gargle, get behind it, and, by its action on the pus, free oxygen and carbonic-acid gas, thus displacing it; the membrane appears under its action to lose all its toughness and crumble. If used in the nose—and it is here where we get wonderful effect—the peroxide had better be made of about ten volumes strength, and if the bichloride is combined with it, make it only gr. ½ to ℥ j, or in very young children still weaker. Before closing, I must add that but a small quantity of the medicine should be bought at a time, as it degenerates rapidly unless kept on ice in a dark place, and not agitated. The hydrogen peroxide losing strength so rapidly makes it very difficult to get pure, so any one who should be disappointed in its action should not give up the use of it until he has surely tried the pure article. It will not, of course, cure all cases. Another point in its favor is, that when used in the throat it causes no pain. The action of the hydrogen peroxide, its thorough antisepsis, and the beautiful mechanical action in forcing pus from cavities, is well known. It should never be used in a cavity unless there is free vent, and especially when this cavity is about the neck; as such a volume of gas is liberated, such an accident as I came very near having is quite possible. An abscess of the parotid gland following scarlet fever had been opened by a small incision. I thought I would wash it out with a little hydrogen peroxide, which I proceeded to do. As a result, I had a tremendously distended sac, the child blue in the face, and nearly suffocated. A large, free incision set matters right in a moment. As an application, and, when the patient is old enough, as a gargle, pure or half and half with listerine, it is the best application in scarlet fever and follicular amygdalitis I know of.

Thiol in Skin Diseases.—"Thiol has been used by Professor Schwimmer, of Buda Pesth, in a large number of skin diseases with remarkable success. In herpes zoster, acne simplex, and rosacea, in moist eczema and in burns, he paints the affected part with a solution in distilled water, of the strength of 1 in 4, twice a day, not washing off the application for two or three days. In some long-standing cases the washing is still longer delayed. In some instances an ointment (1 in 3) was employed, and in other cases the dry powder itself."—*British and Colonial Druggist.*

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, AUGUST 23, 1890.

THE ÆTIOLOGY OF PERITONITIS.

This subject has recently been studied by Fränkel, and a summary of his investigation has been published in the *Centralblatt für Gynäkologie.* The following results were obtained from the investigation of fifteen cases of exudative purulent peritonitis. *Spaltpilze* were demonstrable in all cases of purulent peritonitis. In ten cases chain cocci were found, the same variety of streptococcus being found in nine of them, and more than one variety in two of them. The summary of the investigations contains the list of the different varieties of micro-organisms found, from which it appears that a streptococcus which is well known as an exciter of inflammation was found in all the cases but one, and was probably an important element in producing the disease. After the peritonæum has been infected by the micro-organism which excites inflammation, the morbid process proceeds rapidly and reaches its end quickly, in which case pure cultures of streptococci are found. If the case should not terminate quickly and fatally, other bacteria will wander from the intestine to the peritonæum, and, by means of the products of tissue change which are developed through their influence, will either cause destruction of the streptococci or else so influence their further development that there will be need of the most favorable conditions of nutrition in the bacteriological investigation of the streptococci contained in the exudate in order to produce any results by artificial nourishment outside the body. The author has always succeeded in cultivating the streptococci in a medium of glycerin-agar at an incubation temperature, and thinks that the failures of other investigators may have been due to insufficient precautions. It therefore follows that they were not in all cases justified in saying that the streptococci were absent because they failed to find them.

The streptococcus which has been referred to is considered identical with the streptococcus of erysipelas, and the author succeeded in producing erysipelas upon a dog's ear with it. The other varieties of bacilli which were found had the property of destroying albuminoid bodies, many of them also producing toxic substances which, even after the death of the bacteria, were very virulent to the organisms of animals, while cultures of streptococci which had been subjected to high temperature were harmless. Experiments were also made with chemical agents which produce peritonitis, including solution of iron and tincture of iodine. The resulting peritonitis was sero-fibrinous in character and free from bacteria. If the animals survived some time, gangrene of the intestines resulted with an invasion of bacteria. Prophylactic precautions are mentioned for anticipating peritonitis after abdominal section and in childbed, also the erysipelas which is so destructive to puerperal women.

THE PRESIDENT'S NOMINEE FOR THE SURGEON-GENERALSHIP OF THE ARMY.

The President has sent to the Senate the nomination of Colonel Jedediah H. Baxter to be surgeon-general of the army, to fill the vacancy caused by the retirement of Surgeon-General John Moore. Colonel Baxter entered the volunteer service in June, 1861, as surgeon of the Twelfth Massachusetts Infantry, was appointed surgeon of United States Volunteers in April, 1862, and was promoted successively to the ranks of brevet lieutenant-colonel and brevet colonel, the latter in March, 1865, his promotions having been made on account of faithful and meritorious services in the field. In July, 1867, he was appointed Assistant Medical Purveyor in the regular army with the rank of Lieutenant-Colonel, and was made Chief Medical Purveyor in March, 1872, being promoted to the rank of colonel in June, 1874. The experience of twenty-three years which Colonel Baxter has had in the administrative bureau of the medical department of the army has given him an exceptional fitness for the office of its chief administrator, and the knowledge that he has acquired of the medical needs of the army will, if his nomination is confirmed by the Senate, be of inestimable value to that arm of the service. It is true that other medical officers have a strong claim to the office of surgeon-general by reason of their longer term of service; for, although the ranking colonel, Dr. Baxter's term of service has been much shorter than the terms of several of the officers now in that corps. Nevertheless, with a view only to the fitness of a candidate for the office to which he is nominated, we believe that Colonel Baxter far outranks all others, and for the good of the service we hope to see his appointment confirmed.

MEDICAL AFFAIRS IN CONSTANTINOPLE.

The city of Constantinople has always been a tempting field for the illegal practice of medicine, although there exists a code of regulations which, if faithfully executed, would greatly reduce the number of unqualified practitioners. Under the Supreme Board of Health an official list has been drawn up, containing the names of all legal practitioners, and the pharmacists are forbidden to dispense the prescriptions of any persons not named in that list. As a further precaution, the physicians are directed to write their prescriptions on an officially stamped form or paper, which is issued to them by the Imperial School of Medicine, and which should bear the printed name and address of the prescriber. According to the *Chemist and Druggist*, from which the foregoing has been abstracted, there is probably no town on earth where patent medicines are consumed to such an enormous extent as in Constantinople; the nostrums coming from France take the lead of all others, then follow English, Italian, and German proprietary articles. Street venders dispose of considerable quantities of quinine confec-

tions and pastilles of santonin, and in the bazaars a lively trade is done in drugs for producing abortion, which are used to a large extent by the Turkish and Armenian women. The purchase of opium and hasheesh is almost unknown for private consumption, the trade being exclusively in the hands of wholesale merchants, and it may be observed that, whereas in the seventeenth and eighteenth centuries opium-smoking, in spite of strong prohibitive laws, was very common in Constantinople, very little of that vice is known to exist at the present time.

The Imperial School of Medicine has a strongly patriarchal character, and the tuition is almost entirely free. There are about three hundred students, the majority of whom are clothed and boarded at the expense of the government, but are bound, after the completion of their studies and examinations, to serve for a time in the army, either as pharmacists or as surgeons. The buildings now temporarily occupied by the medical school were formerly used as barracks, but they are beautifully situated in the center of a park, under the direction of a division general. The anatomical collections are exceptionally fine and the school might be described as well appointed and furnished, except for the neglect that is observed in the branch of chemistry, which appears to be the special care or concern of nobody. The chemical laboratory is hardly more than a nominal one, and nearly all the pharmaceutical students have to depend upon private resources for the prosecution of the practical part of their studies. The chemical department is under the direction of a brigadier general.

MINOR PARAGRAPHS.

TELEPHONE INSANITY.

A TALE is told by the Paris correspondent of the London *Daily Telegraph* that may suggest Mark Twain's account of how Hank Morgan's sixth-century wife came to bestow the name of Hello Central on her first-born child. The Paris story is as follows: A lady, about twenty-six years of age, employed in the chorus of one of the theatres, suddenly stopped in the middle of the rue des Petits-Carreaux and shouted at the top of her voice, "Hallo! hallo!" A crowd at once gathered around the young lady, who put her hands to her mouth and ears in telephonic fashion. "Is that you, Saint Peter?" continued she, as if speaking into a tube. "Right, give me my keys? What? You can not be bothered? Then send your commissionaire. I must get home!" She repeated this several times, and at last the spectators came to the conclusion that she was wrong in her mind. A constable took her to the police station, where she went on in the same way, declaring that she heard distinctly through the telephone the celestial music of Paradise, that she could hear Saint Cecilia playing the piano, and that the chorus was composed of cherubim. She was sent into a hospital.

ENTOZOA IN DOMESTIC ANIMALS.

DR. WILLIAM H. WELCH, in the *Johns Hopkins Hospital Bulletin* for July, says that entozoa are of great interest and importance, although they have been overshadowed by the study of pathogenic bacteria, and deserve careful attention. In the course of his examination of animals during the past two years he has obtained from the horse the *Spiroptera megastoma* from the stomach, the *Strongylus armatus* from aneurysms, and the *Gastrophilus equi* from the stomach; from the cow the *Actinomyces bovis* from tumors, the *Cysticercus tæniæ mediocanellatæ* from the heart muscle, the *Strongylus micrurus* from the lungs, and the *Filaria labiato-papillosa* from the peritonæum; from the hog an *Echinococcus* from the liver, the *Cysticercus cellulosæ* from the muscles, the *Echinorrhynchus gigas* from the small intestine, the *Trichocephalus crenatus* from the cæcum, the *Ascaris suilla* from the intestines, the *Sclerostoma binguicolum* from the liver and abdominal fat, and the *Strongylus paradoxus* from the bronchi; from the dog the *Tænia cucumerina*, *Tænia serrata*, and *Tænia echinococcus* from the intestines, the *Eustrongylus gigas* from the peritonæum, the *Strongylus* or *Dochmius trigonocephalus* from the small intestines, the *Trichocephalus depressiusculus* from the cæcum, the *Ascaris marginata* from the stomach, and the *Filaria immitis* from the blood; and from the rabbit the *Coccidium oviforme* from the liver and the *Cysticercus pisiformis* from the peritonæum.

OBSERVATIONS ON THE SECRETION OF BILE IN A CASE OF BILIARY FISTULA.

IN the *Proceedings of the Royal Society* Mr. A. W. Mayo Robson makes a careful report on the analysis and daily secretion of bile in a case of biliary fistula. He concludes that bile is probably excrementitious; that, while it may assist in the digestion of fat, it is not necessary to digest such an amount as is capable of supporting life and nutrition; that increase of body weight and good health are compatible with the absence of bile from the intestines; that its antiseptic properties are unimportant; that its supposed stimulating effect on the intestinal walls is not necessary for regular defecation; that more bile is secreted during the night than during the day; that the excretion is regular and unaffected by diet; that the pigment of fresh bile is biliverdin; and that supposed cholagogues (calomel, enonymin, rhubarb, podophyllin, iridin, turpentine, and benzoate of sodium) do not increase the excretion of bile, though carbonate of sodium in aerated water produces an increased flow.

DISINFECTION BY SULPHUR FUMIGATION.

DR. HENRY B. BAKER, the secretary of the Michigan State Board of Health, has written to the health officer of Detroit a letter called forth by a rumor that the latter was about to dispense with the use of burning sulphur in the disinfection of the rooms and appurtenances of persons affected with diphtheria. It will be remembered that the efficacy of such fumigation has lately been denied in case the sulphur fumes are not mingled with the vapor of water. Dr. Baker maintains that the few laboratory experiments on which this contention is founded should not be held to outweigh the experience of health officers in the restriction of diphtheria. He states, moreover, that it is not necessary to use water with the sulphur, but that the essential thing is to use enough sulphur—three pounds for each thousand cubic feet of space.

THE NEW JERSEY LAW REGULATING THE PRACTICE OF MEDICINE.

WE have heard considerable comment recently on the law of New Jersey regulating the practice of medicine that requires all physicians to pass an examination before a State board of examiners before they can be licensed, and imposes a fine of from fifty to a hundred dollars, or imprisonment for from ten to ninety days, or both, for practicing in the State without a license. The law is virtually the same as that regulating prac-

tice in this State, and to us it seems as fair as could be desired. Certainly it is not surprising that the citizens and physicians of New Jersey should desire the same protection that we have sought for for so many years.

THE DAILY BULLETIN OF THE BERLIN CONGRESS.

Under the general title of *Journal*, with the sub itles *Tägliche Mittheilungen*, *Daily Bulletin*, and *Bulletin quotidien*, a sort of daily programme of the Congress—for it was little else—was published for the use of the members during the session. The matter was arranged in three parallel columns, in German, English, and French. The English is somewhat peculiar, but it is intelligible. The publication is certainly interesting, and not the least charming in its advertising pages, in which "Oberst W. F. Cody" (Buffalo Bill) closes his announcement as follows: "Die Herren Mediciner und Anthropologen seien auf das bedeutende ethnographische und anthropologische Interesse aufmerksam gemacht, das diese Schaustellung während des Anthropologen-Congresses in New York und Paris hervorrief."

A MEDICAL COLLÈGE AT MARSEILLES.

It may seem singular to us that Marseilles, with its population of about four hundred thousand, has no medical college. It has awakened to a realization of its deficiency, and has petitioned the Minister of Public Instruction to authorize the establishment of a medical faculty—a preliminary step toward a university—at the expense of the municipality. The consummation of the desire is being thwarted by the vigorous opposition of Montpellier, that fears for the prestige of its ancient university.

THE COLOR-SENSE AMONG THE CHINESE.

In the *China Medical Missionary Journal* Adele M. Fielde reports an examination of twelve hundred Chinese for the color-sense. Of six hundred women, only one was color-blind—for green; of six hundred men, nineteen were color-blind, and four of these were sons of the green-blind woman. The examinations were made with Thomson's arrangement of Holmgren's test. The results obtained among the men give the proportion usually ascertained in such examinations.

BUBONIC PLAGUE IN TURKEY.

The *British Medical Journal* announces that the Imperial Sanitary Board of Turkey has information of an outbreak of the plague at Kale-Daragehan, a village of two hundred and eighty inhabitants, and that forty-two persons have been attacked, with twenty-six deaths already. The reporter of the cases, Dr. Constantinides, personally observed many of the patients. He states that the disease is marked by inguinal, axillary, and retro-auricular buboes, with a temperature of 104° F. and a bluish cutaneous rash.

THE BRUNSWICK HOME FOR NERVOUS DISEASES.

A private institution at Amityville, Suffolk County, Long Island, named the Brunswick Home, is carried on under State license. It is distant from New York about thirty-two miles. It is constructed on the cottage plan. Persons with nervous or mental disease, acute or chronic, or addicted to alcohol or opium, can be accommodated at relatively low charges. The circular states that $8 to $12 a week are the regular terms for individual rooms. A school for idiotic and feeble-minded persons is embraced in the scope of the Home.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 19, 1890:

DISEASES.	Week ending Aug. 12.		Week ending Aug. 19.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	40	5	40	12
Scarlet fever	28	2	18	3
Cerebro-spinal meningitis	3	2	2	0
Measles	109	8	104	13
Diphtheria	36	11	34	16

The American Climatological Association will hold its seventh annual meeting in Denver, Col., on Tuesday, Wednesday, and Thursday, September 2d, 3d, and 4th, under the presidency of Dr. Charles Denison, of Denver. Besides the president's address, on Abnormal Intrathoracic Air-pressures and their Treatment, the programme includes the following items: Remarks on the Pneumatic Treatment of Disease, with Cases, by Dr. D. M. Cammann, of New York; Bilateral Pleurisy, by Dr. John H. Musser, of Philadelphia; The Physiology and Pathology of Breathing, by Dr. B. F. Westbrook, of Brooklyn; Exhibition of the Pneumograph and Graphic Methods for recording Diseased Conditions, by Dr. J. H. Kellogg, of Battle Creek, Mich.; A Comparative Study of the Climate of those Regions of Europe and America which are now in Vogue in the Treatment of Pulmonary and Nervous Diseases, by Dr. Leonard Weber, of New York; The Climate of Ajaccio, Corsica, by Dr. A. Tucker Wise, of Maloja, Switzerland; The Climate of the Hawaiian Islands, by Dr. Titus Munson Coan, of New York; Is Herpes Zoster a Cause of Pleurisy and Peritonitis? by Dr. R. G. Curtin, of Philadelphia; Report of Cases of Phthisis treated in Colorado, by Dr. S. E. Solly, of Colorado Springs; The Preferable Attributes of Climate for Consumption as applied to the Winters in Southern New Mexico, Southern Arizona, and Western Texas, by Dr. W. M. Yandell, of El Paso, Texas; Information about Desirable Localities for Winter Health Stations in Southern Arizona, by Dr. Thomas Darlington, of Bisbee, Arizona; The Climate of New Mexico as viewed by the Medical Fraternity there, by Dr. James H. Wroth, of Albuquerque; The Climate of the Great Salt Lake Basin, by Dr. A. C. Standart, of Salt Lake City; The Thermal Springs of Salt Lake City, by Dr. George W. Foster, of Salt Lake City; Mental and Nervous Diseases observed in Colorado, by Dr. J. T. Eskridge, of Denver; Mode of Life of the Consumptive Patient in High Altitudes, by Dr. P. B. Anderson, of Colorado Springs; The Relation of Climate to Pulmonary Hæmorrhage in Colorado, by Dr. Jacob Reed, of Colorado Springs; Practical Suggestions with Reference to Exercise of Consumptive Patients in Colorado, by Dr. S. A. Fisk, of Denver; The Injurious Effects of Over-exertion in Pulmonary Phthisis, by Dr. Karl von Ruck, of Ashville, N. C.; The Preferable Climate for Consumption as applied to Northern New Mexico, by Dr. W. R. Tipton, of Las Vegas, N. M.; Climate by Exclusion, by Dr. Francis H. Atkins, of Las Vegas, N. M.; Acclimation of the Consumptive to the Colorado Climate, by Dr. H. O. Dodge, of Boulder, Col.; The Influence of High Altitude Climates upon Youth, as determined by an Acquaintance with the Public-School System of Denver, by Dr. A. Stedman, of Denver; How to select a Proper Climate for Individual Cases of Phthisis Pulmonalis, by Dr. John W. Robinson, of Chicago; Fifteen Aphorisms embodying the Present Status of Pulmonary Consumption, by Dr. J. H. Tindale, of New York; Can Patients in whom Tubercular Disease of the Lungs has been arrested in High Altitudes return with Safety to a Low One? by Dr. Frederick I. Knight, of Boston; Study of Tuberculosis in the Criminal Classes, by Dr. William Duffield Robinson, of Philadelphia; Ocean Climate, by Dr. M. Charteris, of Glasgow, Scotland; The Climate of our Homes, Public Buildings, and Railroad Coaches, a Leading Factor in the Production of the Annual Crop of Pulmonary Diseases, by Dr. R. Harvey Reed, of Mansfield, Ohio; Relations of Certain Meteorological Conditions to Diseases of the Lungs and Air-passages in Colorado, by Dr. Henry B. Baker, of Lansing, Mich.; How far does Dryness of Atmosphere influence the Course or Treatment of Inflammatory Diseases of the Nasal and Pharyngeal Mucous Membranes? by Dr. E. Fletcher Ingals, of Chicago; The Essentials for a Successful "Closed"

Sanitarium in Colorado, by Dr. J. H. Kellogg, of Battle Creek, Mich.; and Selected Cases with Reference to Climatic Treatment, by Dr. H. A. Johnson, of Chicago.

The New Jersey Board of Medical Examiners, recently authorized by the Legislature, is announced as consisting of Dr. William P. Watson, of Jersey City.; Dr. W. L. Newell, of Salem; Dr. Henry S. Wagner, of Somerset; Dr. George W. Brown, of Monmouth; Dr. Hugh C. Hendry, of Essex; Dr. A. Aebalacker (homœopathic), of Morristown; and Dr. Eugene Tiesler (eclectic), of Essex. It is stated that the board will meet for organization on the first Tuesday in September.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 16, 1890:*

Wales, P. S., Medical Director. Detached from the Medical Examining Board and will resume present duty at the Museum of Hygiene.

Ames, H. E., Passed Assistant Surgeon. Ordered as member of Medical Examining Board in addition to present duty.

Sayre, J. S., Passed Assistant Surgeon. Detached from the Navy Yard, New York, and ordered to the U. S. Steamer Ranger.

North, J. H., Jr., Assistant Surgeon. Ordered to the Navy Yard, New York.

Barber, George H., Assistant Surgeon. Detached from the U. S. Receiving-ship Vermont and ordered to the Pensacola.

Wedekind, L. L. von, Assistant Surgeon. Detached from the Pensacola and ordered to the Vermont.

Anzal, E. W., Passed Assistant Surgeon. Assigned to temporary duty at Naval Academy to examine candidates.

Fitts, H. B., Passed Assistant Surgeon. Detached from the U. S. Steamer Pinta and to proceed home and wait orders.

Stone, E. P., Passed Assistant Surgeon. Detached from the U. S. Steamer Independence and ordered to the Pinta.

Whitfield, J. M., Assistant Surgeon. Detached from the Monitor and ordered to the Naval Hospital, Norfolk.

Ayers, Joseph, Surgeon. Ordered to the Naval Academy to examine candidates for admission.

Bright, George H., Surgeon. Ordered to the Naval Academy to examine candidates for admission.

Smith, George T., Assistant Surgeon. Detached from the Naval Hospital, Norfolk, and ordered to the U. S. Steamer Independence.

White, S. S., Passed Assistant Surgeon. Detached from the Marine and ordered to the Naval Rendezvous, San Fraucisco, Cal.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service from July 26, 1890, to August 12, 1890:*

Sawtelle, H. W., Surgeon. Granted leave of absence for fifteen days. August 8, 1890.

Wheeler, W. A., Passed Assistant Surgeon. Granted leave of absence for thirty days. August 5, 1890.

Carmichael, D. A., Passed Assistant Surgeon. Granted leave of absence for thirty days. August 2, 1890.

Peckham, C. T., Passed Assistaut Surgeon. Grauted leave of absence for thirty days. July 28, 1890.

Ames, R. P. M., Passed Assistant Surgeon. Granted leave of absence for fourteen days. August —, 1890. To proceed to Shreveport, La., as inspector. August 5, 1890.

Kalloch, P. C., Passed Assistant Surgeon. Granted leave of absence for seven days. July —, 1890.

Perry, J. C., Assistant Surgeon. To proceed to Wilmington, N. C., for temporary duty. July 31, 1890.

Smith, A. C., Assistant Surgeon. Granted leave of absence for thirty days. August 11, 1890.

Young, G. B., Assistant Surgeon. Leave of absence extended twenty days on account of sickness. August 2, 1890. Upon expiration of leave, to proceed to New Orleans, La., for temporary duty. August 8, 1890.

Stimpson, W. G., Assistant Surgeon. When relieved at Buffalo, N. Y., to proceed to Norfolk, Va., for temporary duty. August 5, 1890.

Letters to the Editor.

BLINDNESS AFTER CEREBRO-SPINAL MENINGITIS.

Cuba, N. Y., *August 15, 1890.*

To the Editor of the New York Medical Journal:

Sir: The case of blindness following cerebro-spinal meningitis with recovery after two years, reported by Dr. W. L. Stowell, is very similar to a case, that of my own brother. Some fifteen years ago he had a severe attack of cerebro-spinal meningitis. After he recovered sufficiently to get about it was found that he was ataxic, and that his sight and hearing were much involved.

He continued in that state without much change for about three years.

At that time he ran against a dipper of boiling water which was being dipped from a boiler into a tub.

All of the breast above the nipples was severely scalded. The scald healed without any unusual symptoms, and with the healing all the former troubles were cured.

He has since grown to be a strong and vigorous man.

H. F. Gillette, M. D.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of April 9, 1890.

The President, Dr. C. K. Briddon, in the Chair.

Appendicitis.—Dr. F. W. Murray presented a young man whose case had been diagnosticated by a dispensary physician as perityphlitic abscess. The patient had come to St. Luke's Hospital, where a similar diagnosis was made. An operation was urged, but declined; on the following day the patient had changed his mind and his abdomen was opened by an incision three inches in length on the outer side of the right rectus muscle. The abdominal tissues were found matted together and thickened. The abscess wall was opened and a quantity of very fœtid pus was discharged. The inner wall of the abscess, which was intra-peritoneal, was formed by a coil of intestine. A smaller cavity was found, from which a fæcal concretion was extracted. It was also seen that the end of the appendix had sloughed away. A counter-opening was made in the loin above the ilium, through which a large drainage-tube was passed into the abscess cavity, which was then packed with gauze. The general peritoneal cavity was washed out and a glass drainage-tube was inserted and secured in the lower angle of the abdominal wound. Iodoform gauze and two sutures were used in closing the wound. The patient had done very well. In three weeks he was out of bed. Now he was perfectly well and had gone back to work. The speaker was rather glad he had made the error of making the incision somewhat too far outside the muscle; but for this he might have opened directly into the abscess and thereby have enhanced the danger of infection of the peritoneal cavity. Another point of note was the good condition of the patient, considering the state of things, and it went to show that it was impossible to predict exactly what would be found until the dissection was made.

Cancer of the Lip.—Dr. Willy Meyer presented a patient, sixty-five years of age, upon whom he had recently operated for cancer of the lip. The growth was very extensive and nearly the whole lip had to be removed except at either corner. Following the method of Dieffenbach, he had taken two flaps from

the cheeks, cutting through the mucous membrane a quarter of an inch above, so that he could approximate both flaps perfectly. It was now ten weeks since the operation, and it would be seen that when the man's beard grew he would present a very good appearance.

Extensive Penetrating Wound of the Thorax; Dislocation of a Rib; Non-collapse of the Lung; Recovery.—The President presented a patient whose case, as reported by Dr. W. H. Ross, was as follows: A man, nineteen years old, a truckman, was brought into the Presbyterian Hospital, in the service of Dr. Briddon, on February 19, 1890. The patient was standing by a horse's head, urging the animal to start with a load of manure, when suddenly the horse turned, forcing the man against a fence, where he received the driving force of the end of the shaft in his chest. The shaft was somewhat pointed, but almost at once its diameter increased to two inches. It was thought that the shaft had penetrated the thorax about three inches.

On examination, it was found that the patient had sustained a wound in the skin two inches and a half by three, with its center over the fourth intercostal space, midway between the nipple and the axilla on the right side. The fourth and fifth ribs were separated to the extent of two inches and a half at the widest point, and the fourth rib was denuded of periosteum for three inches opposite the wound in the skin and displaced upward at the vertebral end. The intercostal muscles were torn asunder for a distance of six inches and the skin and fascia separated from the muscles for a distance of eight inches. The wound of the muscles must have been produced by the forcible separation of the ribs by the cart shaft. There was only partial collapse of the lung. During quiet respiration the lung did not quite come up to the opening, but during violent respiration it protruded through the opening from two to three inches. During inspiration the lung would sink back, and during expiration come up to the opening or protrude from it. The action, therefore, was exactly the reverse of the normal movement. The lung had remained of a pink color. The wound was occluded with iodoform gauze, the ordinary dressing being put on, then covered with rubber tissue and firmly bandaged. Very little reaction followed this serious injury. The temperature never rose above 101° F. There was no suppuration. The wound contracted rapidly and healed kindly by primary union and granulation. On the morning following the injury there was cracked-pot resonance, with many creaking sounds, gurgling râles, and a feeble respiratory murmur over the lung of the affected side. There was a moderate blood-stained expectoration. This ceased in a few days. The respiratory murmur steadily improved and the creaking and crepitant râles became less marked. The patient was able to leave his bed in three weeks, and since then had been about the ward. Physical examination, made six weeks from the date of injury, showed the percussion resonance slightly sonorous over a space three inches in diameter corresponding to the wound in the chest. The breathing was somewhat sibilant there. The difference in expansion of the sides of the chest was only a quarter of an inch. In all other respects the physical examination was negative.

Dr. A. G. Gerster had observed in a case of sarcoma of the rib in which he had seen the pleural cavity opened that when this was done the lung had collapsed and curled up at its edges. A very considerable portion of the pleural cavity had remained full of air. There had been no wound of the lung in that case.

Dr. Gerster, referring to Dr. Murray's case of appendicitis, said he had lately paid a good deal of attention to the distribution of the abscesses which were most frequently met with in this region. In most cases the classical site of selection was near Poupart's ligament, close to the parietal peritonæum. Then the abscess was apt to become subcutaneous, and the opening and drainage was a simple matter. The next most frequent place he had found to be a point corresponding to the right rectus muscle, within the peritoneal cavity and beneath the muscle itself. He had three times made a median incision for exploratory purposes. This incision would tell the surgeon where to attack the abscess so as to avoid opening into the peritoneal cavity. He had not learned to regard with indifference an interference with the peritoneal cavity, and thought that good surgery required that one should try to get at such abscesses without involving it, if possible. To ascertain whether this could be done he had made the exploratory openings, as stated. He believed that the technique of operating properly in perityphlitic abscess was not yet developed, and that this could only follow very careful study of the history of such cases, especially as to the locations most commonly the site of the abscess and the directions in which they tended to spread. The appendix was a very movable body, and certain variations must be expected, but still there were rules which would govern these cases which ought to be studied.

Dr. Robert Abbe thought it was a question as to whether the entire vermiform appendix should be removed in every case. In the event of existing perforation of the distal end only, he should be inclined to leave the stump.

Dr. Murray said he should certainly have removed the entire organ in his case if he could have done so, as he considered it increased the chances of recurrence to leave any of the diseased organ behind.

Dr. Gerster thought that recurrence of true perityphlitic abscesses was not common. Many of the so-called relapses really resulted from imperfect drainage at the first operation and the establishment of sinuses and pockets which favored the redevelopment of abscesses in the presence of any exciting cause. Cases of true relapse did, however, undoubtedly exist.

The President thought the treatment followed by Dr. Murray was the best which could have been adopted. He should hesitate very much to make any dissection in searching for the appendix, lest he might infect the general peritonæum. He would rather risk the recurrence of the disease. It was very important to avoid, if possible, opening into the peritoneal cavity in these abscesses.

Colotomy.—A discussion on this subject having been started, Dr. George A. Peters agreed that the operation should be done as early as possible. He had had more experience with the lumbar operation than with the anterior one. The benefit derived was often very marked. In a case which he recalled, the patient, until he had submitted to it, had been a great sufferer. From that time on, during the three or four months that he had lived, his existence was fairly comfortable. During this period the bladder had become involved and fæcal matter had found its way into the urine occasionally. Still the man had been relieved from all his great distress.

Dr. Abbe suggested the employment of cocaine anæsthesia in these operations, believing that its use would obviate the too frequent fatal results traceable to shock. He had made use of this method in a case some two years before, and with the happiest results. The patient had watched the removal of a large quantity of fæcal matter. Relief from distention had been immediate, and the young man had made a perfect recovery. This patient could not have withstood general anæsthesia and shock. It might not be a suitable method when a great deal of manipulation was necessary. He had employed cocaine three times in opening the abdomen, and in one case *in extremis*.

Dr. B. F. Curtis thought that surgeons were apt to err in the direction of refinements of technique in this operation. It

was not necessary to put in many stitches if the opening into the intestine was not made at the time. Two or three would hold the gut in position with the aid of a stout thread passed through the mesentery.

The PRESIDENT thought it was of decided advantage to make an opening through the muscular tissue. There was less likely to be prolapse, as it acted as a sphincter.

Dr. MEYER said he had performed a similar operation in babies who had been born with imperforate anus. In such cases it was necessary to decide between anterior and posterior colotomy. If the children recovered they were better off with the inguinal opening, as a pad could be more readily applied. Still, the fæces could be better retained after the lumbar incision.

The PRESIDENT said he had never had any trouble after lumbar colotomy. Patients had no trouble in retaining fæces except after some error of diet. Some of his patients were living who had undergone this operation eight or ten years ago.

Dr. GERSTER said he had done the operation quite a number of times and had found it to be a very excellent one. The several steps were comparatively easy under all circumstances. He was one of those who had once incised the small intestine instead of the large one, through the lumbar opening. Since then he had always preferred inguinal colotomy. It put everything in the hands of the operator. As to complications and difficulties, he thought the majority of the cases in which colotomy was done were not those in which the patients were *in extremis*. He thought the operation at one sitting gave the better technical results. The incision should always be transverse. He had had some cases of prolapse and they were very disagreeable. To avoid this, care should be taken to select a piece of mesentery of proper length. If it was too large, the gut should be dragged back and another section of intestine sought for with a mesentery of suitable length.

Tumor of the Bladder diagnosticated with the Cystoscope.—Dr. MEYER presented a tumor which he had removed from the bladder of a patient fifty-five years of age. In this case the diagnosis had been made by means of the cystoscope. The patient had suffered for a long time from hæmaturia. When consulted, the speaker, instead of using a sound to search for stone, had at once tried to introduce the cystoscope under cocaine anæsthesia. This he had found impracticable, and three days subsequently had given the patient chloroform. He had then made out with the utmost certainty the growth on the left wall of the bladder. He could also see the blood oozing from it. The result of the operation had been to confirm the diagnosis so made. The tumor, on being removed, was found to be malignant.

RICHMOND, VA., ACADEMY OF MEDICINE AND SURGERY.

Meeting of July 8, 1890.

The President, Dr. W. W. PARKER, in the Chair.

(*Reported by Dr. J. W. Henson, Richmond.*)

Speech and Locomotion Absent in a Child Three Years and a Half of Age.—Dr. J. N. UPSHUR reported the history of a case of a child unable to walk or talk at the age of three years and a half, although apparently perfectly developed physically and to a casual observer as bright mentally as any child—in reality, however, being several months or a year behind the average. The expression of its face was a little more childish than the age demanded.

There was, he said, a remarkable suppleness about the hip joints, the child being able to abduct the lower limbs until at right angles with the trunk, or flex them until flat upon the abdomen. It possessed a good appetite, was perfectly well nourished, though constipated, and had resisted well two or three severe attacks of sickness. It had a remarkable aptitude for the appreciation of musical sounds. The child's teeth exhibited great irregularity in their manner of eruption, appearing here and there at haphazard around the dental arch.

The speaker knew of no cause for the state of affairs, except that the mother, when pregnant with this child, was subjected to considerable mental and physical worry on account of the illness of an older one. He would like to know the chances of its attaining the power of speech and locomotion. Was the condition the result of lack of nervous power, and would benefit accrue from the use of electricity and massage?

Dr. J. MICHAUX asked if there had been any convulsions.

Dr. UPSHUR replied that there had been none.

Dr. C. L. CUDLIPP asked if all the pelvic bones were normal.

Dr. UPSHUR replied that they were.

Dr. MICHAUX thought the case one of arrest of development from lack of brain or nervous organization, and that there was little chance for mental development under such conditions.

The PRESIDENT thought that a child of three years would learn to talk.

Dr. GEORGE BEN JOHNSTON believed the case, from the history, to be one of mild rickets, and he was sure that by an active tonic treatment in which the hypophosphites were involved, massage (particularly), electricity, and strict attention to hygienic surroundings, much good could be done for the child's bones. He thought it would walk, and did not believe the inability to speak necessarily serious.

Veratrum Viride in Puerperal Convulsions.—The PRESIDENT reported having used in a case of puerperal convulsions, occurring two or three weeks before the expected time of labor (besides the usual plan of venesection and chloroform), tincture of veratrum viride, administering fourteen drops early, and afterward five drops every two hours. Dr. Hugh M. Taylor, in consultation, had recommended enemata of bromide of potassium and hydrate of chloral in large doses. The patient was successfully relieved, but labor commenced two or three days afterward, and under chloroform the patient gave birth to a live child of eight months' gestation, large but feeble. The speaker had great faith in veratrum viride for the relief of convulsions.

Dr. ALBERT SNEED had recommended it in ten-drop doses every two hours.

Cholera Morbus rapidly Fatal.—The PRESIDENT stated that a Mr. V. had summoned medical aid about 2 A. M. on Wednesday. By 3 P. M. on Thursday he was dead. Before death the vomiting and purging became excessive, and a convulsive movement of the lower extremities manifested itself. The victim had been robust and perfectly healthy all of his life, except for an anal fistula some years ago. The speaker had been the family physician, but, being out of town, another doctor was called, who reported the case to him. He thought the action of the vagus had been inhibited by the intense heat, the man's work keeping him much in the sun.

Chloroform vs. Opium in Intestinal Inflammations.—A short time after V.'s death, continued the PRESIDENT, his son was stricken down. After the first day or two of illness he complained of very little pain. The speaker, accepting the case only the day before death occurred, found him quiet, pulse 120, and temperature 101°; but, though there was no pain, except upon deep pressure, it was then severe and the abdomen was retracted—two bad features. Late the next day the boy was in collapse, death soon following. A post-mortem examination revealed the ascending colon pushed obliquely across the abdomen by the greatly distended and inflamed small intestines,

which here and there showed adhesions and exudations (some as large as a fifty-cent piece) about to undergo organization. In fact, a severe general peritonitis had existed, a pint of pus being in the cavity of the peritonæum.

The speaker believed the lack of pain due to the amount of morphine given by the physician first in charge. He objected to such large doses of the drug, and mentioned in connection a fatal case of intestinal inflammation to which he had been called at Old Point. The physicians called in before him had probably administered large doses of morphine. He found the man in collapse, perfectly quiet and indifferent. No amount of stimulation or other means used produced any reaction. He believed large doses of opium would not only prevent reaction, but increase congestion. He thought the pain of these cases very largely due to spasm of the muscular layer of the bowel, and therefore would just as readily and much more safely be relieved by chloroform (by inhalation and internally), together with stimulants.

Dr. Johnston asked if there was any *débris* of food in the colon, particularly about the cæcum, in the post-mortem case mentioned.

The President replied that there was none.

Irritation from Calomel and Castor-oil.—Dr. Upshur believed there was something back of the opium in the president's case. He thought the purgative action from large doses of calomel (such as fifteen grains) and the castor-oil following it would add to the irritation and congestion. The kind of congestion referred to by the president would be aggravated by opium, but he considered the drug beneficial in passive congestions, such as occurred in the latter stages of typhoid fever. He had been interested in the president's case of puerperal convulsions, because the child was born alive. He always expected a dead child after convulsions. The speaker believed it the imperative duty of every physician to make periodical examinations of the urine of pregnant women in his charge, and to inquire into the amount of water passed *per diem* and the condition of head and vision. There might be double vision, intense headache, and scanty urine without albumin, and yet convulsions. He remembered a patient of his who complained of severe headache two weeks before confinement, no albumin being present and no impairment of vision. Just after completion of labor she had been threatened with convulsions. The prompt and continued use of chloroform, however, had warded off the attack. The skin had been hot and dry. Bromide of potassium and pilocarpine were administered in repeated doses, until a profuse perspiration was induced, with relief of head symptoms. Examination of the urine now showed thirty-three per cent. of albumin. The patient had made a complete recovery. He mentioned another case in which he had had the same experience with pilocarpine. He knew the objection to it—that it was depressing; but why object to it, and recommend veratrum viride? For the immediate relief of convulsions he used morphine and atropine hypodermically, besides the lancet and chloroform.

Dr. Landon B. Edwards thought that Dr. Upshur had given the true cause why some physicians had so many cases of puerperal convulsions. The maxim of Dr. Owen, of Lynchburg, was: "Watch the woman as you would the training of a child." Though convulsions did not always follow the symptoms, yet they should be accepted as warnings.

As a prominent symptom he mentioned the morbid appetite in the latter stages of pregnancy. First quiet the alarm of the patient, then direct attention to the kidneys. He, too, highly recommended pilocarpine if the patient was strong enough to cough up or call attention to the accumulation that would occur in the bronchial tubes.

Erratic Pain in Labor.—Dr. Johnston had been called, fifteen or twenty days before her expected delivery, to a woman, the mother of four children (good labor each time), who complained of a severe pain, paroxysmal in character, occurring on the right side of the neck and extending down upon her chest to the margin of the axilla. The speaker, suspecting the approach of labor, asked an examination, but was refused. Early the next morning he was called again, and found the child born. The pains had increased in length and intensity, the intervals growing shorter until there was suddenly a gush of waters, the birth of the child immediately following. The woman had not a single uterine or abdominal pain, and did not in the least suspect the real condition of affairs.

Scirrhus of the Rectum in a Child of Thirteen Years.—Dr. Michaux had been treating a child of thirteen years for ulcerated rectum for some time with no benefit. He had decided upon an examination of the parts, which he had made with the patient under chloroform. About two inches above the anus he had found a band two inches and a half in width nearly closing the caliber of the bowel. It was hard to the touch, but tore upon pressing the finger through it. There was some inguinal enlargement. Every motion of the bowels caused violent pain, and this examination induced so much as to render the use of opiates necessary. The general appearance of the boy suggested malignancy, and the doctor believed it such, though he had never seen or known of a case in so young a subject.

Dr. Upshur, refusing to believe in malignancy at that age, thought Dr. Michaux would find that some previous proctitis had produced the band of lymph present, or that there was some history of syphilis back of the trouble. He had seen such a case in a woman of decided syphilitic history, there being acute pain upon defecation. He had performed repeated cuttings and dilatations. Her health had ultimately given out, death following soon. He would suggest alteratives, such as iodide of iron, etc., and nutritious but fluid diet. The rectum might be washed out with warm water and boric acid. The pain could be relieved by suppositories medicated with cocaine or enemata of glycerin and cocaine.

Dr. Wheat thought Dr. Michaux had better look after a probable syphilitic history. He related the histories of two cases of his own. He found that a constitutional treatment involving potassium iodide particularly gave decided relief. Though the trouble returned, this treatment relieved each time. He had no faith in operative measures in such cases. Had tested that plan.

Dr. Michaux had neglected to say that the child's grandfather had died of cancer. He would, however, take advantage of the encouraging suggestions. He would obtain some of the growth for microscopic examination.

[Since the meeting Dr. Upshur has found, upon stripping the little girl of three years and a half whose condition he reported, that there was a uniform atrophy of the muscular system. He has given her the benefit of massage and electricity for ten days. Improvement has manifested itself by the more ruddy appearance generally, and the toning up of the muscles.]

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION IN PATHOLOGY.

Meeting of May 2, 1890.

The President, Dr. E. H. Bennett, in the Chair.

Diphtheritic Micro-organisms.—Dr. McWeeny showed a section through the epiglottis of a child who had died in the

Mater Misericordiæ Hospital from post-scarlatinal diphtheria. The patient had been admitted in the desquamation stage of scarlatina suffering from a bad throat and albuminuria. After death the mucous membrane of the upper part of the larynx was found coated with a thin layer of greenish-gray exudation.

The sections exhibited showed numerous micro-organisms in irregular masses, and also scattered through the almost structureless membranous exudation. Some of these were cocci, others bacilli; the cocci were scattered or in pairs, the bacilli were smaller in size than the Klebs-Löppler diphtheria bacillus, and were certainly not the same species, as, in addition to the difference in size, they also differed in the fact that the bacillus found by Dr. McWeeny stained readily by Gram's method, whereas the Klebs-Löppler organisms was at once decolorized by iodide of potassium. Cornil and Babes also described organisms found in cases of pseudo-diphtheritic laryngitis after scarlatina, but they seemed to have found chiefly cocci.

Dr. McWeeny also showed a cover-glass preparation of a pure culture of the Klebs-Löppler diphtheria-bacillus showing the so-called "involution forms," and referred to the recent researches of Spronck into the subject, which had quite established its pathogenicity. A sterile filtrate of a pure culture would cause paralysis closely resembling the metadiphtheritic in the human subject, and also albuminuria in rabbits.

Multiple Abscesses of the Liver.—Dr. Joseph Redmond submitted a case of multiple small abscesses of the liver.

Mrs. E., a married woman, was admitted into the Mater Misericordiæ Hospital on the 27th of February, 1890. The patient was anæmic, wasted, and somewhat jaundiced in appearance. She complained of severe pain over the liver, and stated that she suffered from gall-stones. Her stomach was irritable, no food having been retained for some days, the vomited matters yellow and bitter to the taste. The bowels were constipated, and the last motions observed were somewhat light in color. Her tongue was furred; temperature, 98°; pulse, 100; respirations, 24. The liver was enlarged and tender on percussion. The spleen was also enlarged, and could be felt below the ribs. Some days after admission she suffered from rigors; temperature, 103°; pulse, 148; respirations, 36; signs of pleuritis being detected over left bases. The patient died on the 12th of March.

The post-mortem was made by Dr. McWeeny. The right and left pleural cavities showed evidence of acute inflammation The liver was enlarged; numerous small abscesses were detected, more especially in the left lobe. The gall-bladder was full of small angular calculi. The cystic duct was thickened but patent. The common bile duct was blocked by a calculus lying immediately behiud the duodenal mucous membrane.

Dr. McWeeny said that he suggested the somewhat wild hypothesis that the gall-stones might have caused ulceration of the common bile duct, and that micro-organisms might have made their way up, in spite of the supposed antiseptic action of the bile, and spread into the ordinary liver substance; but his belief was that the case was pyæmia.

The President said he regarded the abscesses in question as pyæmic.

Dr. Redmond, in reply, said he had no remark to make save that the gall-bladder contained no pus.

Round-celled Sarcoma of the Testis.—Dr. McWeeny showed a tumor of the testis removed at the Mater Misericordiæ Hospital in January last by Mr. Chance. The patient, aged about thirty, had first noticed the swelling about two years previously, and it had since increased gradually aud painlessly with absence of testicular sensation. No tubercular or syphilitic history of patient or family; no history of injury. The testis was enlarged to the size of a medium-sized orange; its shape was globular; its consistency hard. On section, the substance was white, mottled with yellowish patches, which looked to the naked eye like caseated portions, and which on microscopic examination were fatty degenerated and almost devoid of structure. There was no trace of tubercular new growth. The white tissue consisted of *cells* and a *stroma*. The *cells* were largish, oval, uni-nucleated, and offered little or no variation in size or shape. They did not lie in actual contact, but each was separated from its neighbor by a small quantity of homogeneous intercellular substance. Their characteristics were, on the whole, those of the connective tissue rather than of the epithelial type.

The stroma was trabecular in character, the main trabeculæ being comparatively thick and running a straight course through a considerable part of the sections. From them were given off more delicate bands, which in their turn gave origin to still more delicate ones—the same structure prevailing throughout—viz., round and spindle-shaped nuclei of various sizes, with little or no approach to the formation of fibrous tissue. The ultimate trabeculæ consisted of but one or two rows of spindle cells placed side by side and end to end. They were clearly distinguishable from the oval cellular elements above mentioned, which lay in groups of varying size—about a dozen together as a rule—in the ultimate meshes of the stroma. He was in some doubt as to whether the stroma did not represent that which, in the normal testis, starting from the mediastinum, runs between the lobules—in which case it would seem to have increased *pari passu* with the tumor, or whether it was of entirely new formation, in which case the specimen would have to be looked upon as one of alveolar sarcoma—a neoplasm of some rarity in that situation.

Dr. Patteson said that, judging from the general distribution of the stroma and the character of the cells, this disease was much more distinctly a carcinoma than a sarcoma.

SECTION IN SURGERY.

Meeting of May 9, 1890.

Mr. Edward Hamilton, F. R. C. S., in the Chair.

The Surgery of the Brain.—Mr. Thornley Stoker read a paper on two cases of brain disease on which he had operated during the session.

The first he detailed was treated jointly by Dr. O'Carroll and himself. It was a case of abscess in the right temporal lobe, depending on disease of the ear. Pain, retraction of the head, and right anosmia were the leading brain symptoms. The patient, a girl of eighteen, was dying from pain, and operation was determined on, although symptoms did not show clearly whether the temporal lobe or the cerebellum was the seat of disease. On March 9, 1890, the brain was exposed with the view of exploring the cerebellum, if pus should not be found in the temporal lobe.

The trephine opening was placed, with the purpose of exposing the second temporal convolution, with its center an inch and a quarter behind the external meatus and an inch and a half above this base line. Mr. Thornley Stoker spoke of the mistake made by Mr. Barker in placing the point to expose the second convolution too low down—viz., an inch and a quarter above the base line—and he demonstrated, by a number of Professor Cunningham's models and drawings, kindly lent for the occasion, that the point indicated by Mr. Barker could only expose at the highest the inferior convolution, and might even endanger the lateral sinus. He expressed his intention in future of operating an inch and three quarters above the base line, at

which height only there would be reasonable certainty of exposing the second convolution.

Nine exploratory punctures were made in different directions, and on the ninth, at a distance of an inch and a half from the surface of the brain, pus was found, to the amount of two to three drachms, lying above the tentorium, in a direction downward, inward, and backward from the trephine opening, at the junction of the under surfaces of the temporal and occipital lobes.

The patient, who had passed through several dangerous and interesting periods since operation, was now, three months after the trephining, alive and doing well. And, although she had lost several drachms of brain matter by sloughing and by the removal of a hernia cerebri, she suffered no paralysis or impairment of any kind, the sense of smell being restored and all her symptoms relieved.

The second case, treated jointly by Dr. Nugent and Mr. Thornley Stoker, was one of a spindle-celled sarcoma of small size situated in the superior and back part of the right parietal lobe of a man aged forty-two.

It had given rise to tonic spasms of the left side, commencing in the leg and gradually invading the trunk, upper extremity, and face. Spasm was followed by paralysis, occurring in the same order from below upward.

The patient was operated on, the leg and arm centers being exposed, but the tumor was not discovered, as it lay at the extreme back of the leg center, and was of the same consistence as the brain substance, so that instruments passed through it without resistance. The removal of pressure afforded by the operation gave temporary relief. The patient, who was nearly comatose and quite hemiplegic, recovered consciousness and partial power in the side, but died three weeks afterward.

The chief points of interest in the case were: 1. The irregular position of the spasms, which sometimes engaged the upper extremity without the lower, although the tumor proved to be remote from the arm center. Mr. Stoker dwelt on the matter of what he termed "referred" pressure as an important and confusing factor in such cases. 2. That the position of the tumor pointed to the extension backward of the leg center into what had been regarded as a doubtful region. 3. That the case showed the leg center to be behind that for the thigh. 4. The absence in this instance of three of the four classical symptoms of brain tumor—viz., optic neuritis, fixed headache, and vomiting; only the fourth, hemispasm, being present.

Dr. Birmingham communicated a preliminary report of an investigation which he was carrying on into the surgical anatomy of the parts engaged in the operations of trephining in mastoid and tympanic disease. The following were the chief objects kept in view in the investigation: 1. The anatomy of Mr. Wheeler's operation, which opened the cranial cavity and the mastoid cells at the same time by one trephine hole. 2. The exact relation of the mastoid antrum to the surface. 3. The position of the lateral sinus, how to find and how avoid it. 4. Whether there was (anatomically) any danger in opening the mastoid cells immediately behind the meatus. Many specimens were shown illustrating the points considered, and a full report was promised in a short time.

The Chairman observed that before brain surgery could make any steady, useful advance there must be something like anatomical certainty; and he regarded the contributions of Mr. Stoker and Dr. Birmingham as valuable anatomical data.

Mr. Patterson said he had himself, like Mr. Stoker, proved the unreliability of Barker's lines. He had had a case in St. Vincent's Hospital in which it was decided to trephine the temporal lobe of the brain; and taking a quarter of an inch higher than Barker's line in order to make perfectly sure, he had had great difficulty in removing the disc of bone, and when he succeeded he found that the lateral sinus was exposed and occupying one third of the available space, thus showing clearly that Barker's lines were unreliable. A limited post-mortem examination proved that the diagnosis was unfortunately incorrect, and that the case was one of long-standing otorrhœa; but the course adopted seemed to be the only possible one of saving life. However, as applicable to the surgery of the brain, the point was that the lines of demarkation chosen resulted in exposing about half an inch of the upper border of the inferior temporo-sphenoidal convolution.

Mr. Tobin, referring to Dr. Birmingham's observations, recalled Mr. Wheeler's remark on reading his communication to the section as being to the effect that the opening which he made was one from which the tympanum might be reached, and not one for the purpose of exposing the tympanum. As regarded Mr. Stoker's communication, he asked, assuming in the first case detailed that the abscess was secondary to caries of the temporal bone, whether it would not have been advisable, after reaching the abscess, to adopt means for getting rid of the primary disease, so that further secondary abscesses might not form. Thus, a secondary trephining operation might be adopted for the primary disease. Another moot point was as to the advisability of using the aspirator to empty a pus cavity of the brain, the tendency of the structure being to break down and, from the use of the aspirator, to give rise to more pus.

Mr. Stoker, in reply, was glad to find that his observations had been indorsed by Mr. Patterson's experience. There could be no doubt that an examination of Professor Cunningham's diagrams and casts would show that, instead of going an inch and a quarter above the horizontal line, as Barker recommended, or an inch and a half, as he himself had gone in one of the cases under consideration, the operator might go an inch and three quarters. He cordially agreed with Mr. Tobin's view as to the desirability of treating the primary disease; and in operating in the case of the temporal abscess, he was prepared to trephine the mastoid process with that object, but he did not find it desirable for several reasons. He looked forward to doing it, as at present the ear was suppurating, and required to be washed out twice daily with corrosive-sublimate solution. It was obviously proper to remove the cause of the disease, as well as the secondary evidence of it. As regarded the use of the aspirator, the case was one of the first in which he operated for an abscess in the brain, and he used the aspirator, but with the result that he made up his mind that he ought not to use it again; that it was calculated to do violence to structures, and that it was totally unnecessary. The brain exercised such pressure that as soon as the abscess was opened it closed the walls together, and the pus was pushed out with as much force as was desirable. So that the aspirator was unnecessary and might be injurious.

Dr. Birmingham, in reply to Mr. Tobin's remark, said he adopted Mr. Wheeler's published description as the basis of his observations.

Section in Medicine.

Meeting of May 16, 1890.

Dr. John William Moore in the Chair.

Acute Confusional Insanity.—Dr. Conolly Norman read a paper on acute confusional insanity. He pointed out that this form of psychoneurosis occupied an intermediate place between acute mania and the acute dementia of the older classificatory schemes, and contained a very large number of cases. It was characterized by engagement of consciousness in the form of

dream-like confusion, together with hallucinatory disturbance. It was interesting to others than specialists, because it was the form of mental disturbance most often associated with diseases not primarily affecting the nervous system. Puerperal, post-febrile, rheumatic, phthisical, and other varieties of insanity depending on general diseases commonly took this form. Dr. Norman dwelt upon its frequency in alcoholic cases, and pointed out that the peculiar mental disturbance described by Korsakow, Ross, and Viglesworth as accompanying alcoholic neuritis was a variety of acute confusional insanity. He detailed a number of illustrative cases, including several alcoholic ones, and defended the differentiation of this affection on ætiological and prognostic grounds, as well as because the distinction tended to more accurate clinical description.

Dr. Moloney inquired whether, firstly, in the younger persons whose cases had been detailed, the state of the heart and kidneys had been examined; and, secondly, in the older persons, particularly in the case of the woman who fancied a black man came into her room at night, whether there had been any uterine trouble, or the climacteric time had been reached. He had himself observed a considerable number of cases in which, at the climacteric time of life, there was confusion as to dates and places, and also, most commonly in cases of the melancholic type, delusion of persecution by unseen agents. One woman's insanity commenced with the hallucination that somebody was outside at the gate shouting that she was too fond of going into her father's bedroom (her father was suffering from bladder trouble) and that such conduct was indecent. At the outset she exhibited maniacal excitement, and for several months she was rather confused in identifying those about her, being doubtful whether her nurse of to-day was the nurse in charge of her the previous day, and doubtful also of his (Dr. Moloney's) name, while identifying him sometimes by his boots and at other times by his hat.

Dr. Norman, in reply, said there was no heart or kidney affection in the younger patients; at least, though anxiously searched for, none was discovered. The woman who came to Dublin to consult her lawyer was aged fifty, and had ceased to menstruate at forty-seven; but there was no indication of uterine trouble. He was inclined to think that to the type which he had described belonged the case mentioned by Dr. Moloney. Cases of the kind seemed to vary in character between mania and melancholia, giving rise to difficulty of classification; but in the asylum such classification was not so important for purposes of treatment as to comply with the desire of the Psychological Society, there being what was called in asylum slang a "refractory ward," into which cases that would not go anywhere else were inevitably put.

Medicated Soaps.—Dr. Walter G. Smith made a communication upon medicated soaps. He drew attention to the differences in preparation and properties of soda and potash soaps, and pointed out the injurious effects upon the skin of an excess of alkali, which not only removed the greasy dirt but also robbed the skin of its natural fat. This was derived from two sources—(*a*) the glands, sebaceous and coil glands; (*b*) the eleidin of the epidermis. Over-fatty (super-fatted) soaps—*i. e.*, containing some unsaponified fat—represented a real advance in the preparation of good soaps for medicinal use. The composition of "Grundseife" (basis-soap) was: Beef suet, 59·3 per cent.; olive-oil, 7·4 per cent.; soda lye, 38° Beaumé, 22·2 per cent.; potash lye, 11·1 per cent. This could be medicated by a variety of drugs—*e. g.*, resorcin, ichthyol, sulphur, mercurials, etc. The detergent action of soap was explained, and the modes of using medicinal soaps were commented upon.

Dr. McVeagh said that to dermatologists medicated soaps had many recommendations for the treatment of parasitic diseases; and he expressed great faith in corrosive-sublimate soap for eczema in children, rubbing it in and then putting on a thin gauze.

Dr. S. M. Thompson inquired whether salicylic acid might be used in soap for eczema of the head in children without causing irritation.

Dr. William Stoker, having regard to the limitation of the medicated soaps chiefly to the soaps composed of the fatty acids in which the alkali had replaced the glycerin, inquired as to lithium soap; secondly, in view of the explanation of the action of soap on the hands in the ordinary method of use, whether it was equally true of the super-fatty soaps that there was free alkali in free dilution; and thirdly, whether it was competent in the glycerin soap to retain much of the glycerin as used in commerce, or was it only "glycerin" so called on the *lucus a non lucendo* principle. He had been informed by a Dublin manufacturer, on the surface of whose soap he noticed globules, that almost all the glycerin was retained in the soap.

The Chairman said he had seen an ointment containing ten grains of salicylate to the ounce used even on children without deleterious effect. As regarded the question whether glycerin was really present in so-called "glycerin soap," the sweet taste of that soap was conclusive evidence of its presence.

Dr. Smith, in reply, said, as regarded Dr. Thompson's inquiry, that the question was one for the practitioner's judgment. As to Dr. Stoker's questions, he had no knowledge of lithium soap. The transparent glycerin soap contained a large amount of glycerin. He had not had time to make an analysis of the vinola soap. There was no doubt that the use of medicated soaps represented a distinct advance in the methods of treatment.

Old Fallacies revived under New Names.—Dr. T. More Madden read a paper on the recent revival under new names of some old fallacies bearing on medicine.

A recurrence of epidemic empiricisms widely affecting the practice of physic had been often observed in the history of our art. These popular beliefs, however fallacious their foundation, generally died hard, and, after a period of oblivion, were not infrequently resuscitated. Thus at present we had at least "three Richmonds in the field," where medical science and its counterfeits were in close competition, and where the prize of ephemeral success was perhaps most frequently awarded to the latter. These rival popular therapeutic theories, methods, or "*fads*" included hypnotism, massage, and faith-healing, each of which might be considered as being in some measure illustrative of the revivalism just referred to, with the exception of the latter. Faith healing rested on religious belief, and therefore, however erroneous or fanatical it might be, it could not be properly classified in the medical journal. Hypnotism and massage could claim no such exemption from full discussion and criticism, although in some respects it might perhaps be difficult to treat their pretensions seriously. First, with regard to *hypnotism*. Under that term had apparently been recently confounded and intermixed the resuscitated phenomena of two essentially distinct conditions—namely, that modification of animal magnetism with which the name of the late Mr. Braid, of Manchester, was formerly associated—*i. e.*, Braidism; and, secondly, with this, in some instances, were now conjoined the revival in a new guise of the older illusions of mesmerism. Of the possibility, in many cases, of producing by the former a state of concentration or anæsthesia in which surgical operations might be painlessly performed there could be no question. The expediency or prudence of availing ourselves of this power, especially in the cases in which it might most commonly be exercised—namely, in the case of patients of abnormal mental or nervous constitution, such as those of hysterical temperament, of whom the

number, male as well as female, was larger than was generally supposed—was another question, and one which Dr. Madden thought should be unhesitatingly answered in the negative, for various reasons, physical and moral, which he assigned. With regard to the still more objectionable and more remarkable alleged powers by which, as had been again recently asserted, the skilled operator in this occult art might, at his will or by his mental suggestion, or induction, of a subtile nerve force, somewhat akin in its supposed action to the magnetic influence, control the thoughts and acts of the hypnotized subject, and even thus modify the course or arrest the progress of disease—these, although, as just said, very commonly confounded with Braidism, were obviously traceable to the older illusions of animal magnetism or of mesmerism, of which they were substantially the resuscitation in a new guise. The real marvel connected with such assertions appeared to be the fact that at the present day some men of whose sincerity and sanity there could be no possible question should claim these powers, and that others similarly circumstanced should admit the possibility of their influencing any persons save those of abnormal nervous or mental constitution, more especially the oftentimes semi-insane victims of hysteria. *A priori*, it might well seem incredible that pretensions of this kind should be gravely advanced and accepted in the last decade of the nineteenth century, were it not that this age, so often skeptical of the truths of Divine Revelation, had afforded so many illustrations of its credulity in the illusions of pseudo-scientific enthusiasm; and that at the present time we had abundant contemporaneous evidence of a widespread credence in the alleged and incomprehensible powers of animal magnetism, as asserted, under the name of hypnotism.

To deny *in toto* the possibility of phenomena to the actuality of which so many witnesses had testified, merely because they were apparently at variance with common sense and wholly inexplicable in the present state of our knowledge, might perhaps be thought unphilosophical. Hence, whatever our own opinion might be on this subject, we must be content to leave its final decision for the eventual judgment founded on the better knowledge and experience of the profession. Whatever that verdict might be, it could not be very long delayed.

The painful exhibitions of so-called hypnotic influence described in recently-published reports of certain proceedings on the Continent, as well as the spectacles of either fanatical enthusiasm or else of charlatanism acting on acquiescent imbecility which he had himself more than once witnessed in the performances of professors of animal magnetism, could hardly be spoken of from any point of view save in terms that might perhaps be deemed offensive by those who were believers in these powers. Hence he would forbear any further reference to them. For, as the learned Fuller had long since observed: "I meddle not with these Bedlam phancies, all whose conceits are antiques, but leave them for the physician to purge with hellebore."

Dr. Madden then discussed the pretensions of massage to novelty, and entered at considerable length into the history of some persons whose methods of cure, as successfully employed in Ireland so far back as the days of the Commonwealth, and subsequently in the time of Charles II, were, he thought, largely anticipatory of the present practices of massage, as well as those of animal magnetism or hypnotism.

Whether such phenomena, ancient or modern, had any foundation in actuality it would be difficult as yet to pronounce. There were more things in heaven and earth than were dreamed of in our philosophy, and these might be of them. At any rate it might be interesting to bear in mind the success, in one respect at least, that rewarded the original professor of animal magnetism, whose career might possibly be some encouragement to the modern practitioners of hypnotism, and to remind them that upward of a century ago somewhat similar pretensions were made by Mesmer, whose thesis *On the Influence of the Planets on Human Bodies* was published in Vienna in 1776. Whether Mesmer appropriated the views previously held on this subject by the Viennese astronomer, Hehl, as the latter maintained, or not, now mattered little. The controversy between the learned professor of unsavory name and the reputed father of animal magnetism was a very animated one, and contained some curious matter. The result of the discussion was Mesmer's retirement from Vienna to Paris, where, two years later, in 1778, he reappeared on the stage as the then reigning lion of Parisian society as well as the most successful practitioner of his occult art—from both of which positions his fall was as signal and as rapid as his rise thereto had been. While the brief sunshine of his popularity lasted, however, Mesmer, who apparently had always a shrewd eye to the main chance, acted on the old adage so successfully that within a couple of years he realized by his practice in Paris a fortune of some 340,000 livres, and before the publication of the adverse report of the commission appointed to investigate this question managed to sell the secret of his method for a sum equivalent to fourteen thousand pounds. The modern professor of animal magnetism might well regret the palmy days of the Ville Cour.

Dr. A. N. Montgomery said, with reference to massage, that it was a pity Dr. Madden had not attended the previous meeting of the Section, at which an exhaustive paper on the subject was read by Dr. Kendal Franks, who traced its origin to many years prior to the Christian era, and advocated taking the treatment out of the hands of quacks and charlatans and putting it on a scientific basis, which he had explained. It was also to be regretted that Dr. Madden, in sending in the title of his paper, had not specified the *fallacies* which he intended to discuss.

Dr. Norman said that about massage he knew little; but since it had been prescribed by some enthusiasts in late years as a universal remedy in mental diseases, he fully shared in the terms of contempt and scorn with which Dr. Clinton, of Edinburgh, had referred to the curative powers alleged for it in mental disease. That mesmerism had taken the course it did was unfortunately due to the attitude adopted toward it by the medical profession in the time of Mesmer—denying the truth of certain things which were undoubted facts. But since the days of Heidenheim, and since Charcot's investigations, the faculty looked upon what was now generally called hypnotism in a more serious way. That there was some truth in the phenomenon everybody knew, but that hypnotism had the therapeutic effects ascribed to it, he agreed with Dr. Madden was incredible and absurd. He had learned that Charcot was now withdrawing from the practice of hypnotism, conceding that its certain evil effects counterbalanced any good that might be expected. Voisin, the author of a famous treatise on several diseases common to the insane—amenorrhœa, epilepsy, masturbation, lying, thieving, and moral insanity—was under the delusion that these diseases could be cured by its means. It was almost enough to overturn one's mental balance to broach the idea that moral depravity could be cured through the agency of hypnotism. As a warning of the danger of hypnotism, Heidenheim's first and favorite subject was his own brother—a fine, active, healthy young man, who, under the constant strain of hypnotic experiments, fell into a state of neuro-anæmia, became incapable of following his profession, and had to take a holiday of two years' duration before he recovered his mental tone. He had read a recent case in a German medical journal recording the details of a woman who fell into the hands of a hypnotic quack and was hypnotized into a state of acute confusional insanity.

Reports on the Progress of Medicine.

ANATOMY.

By MATTHIAS L. FOSTER, M. D.

Congenital Sacculations and Cystic Dilatations of Veins.—These conditions bave from ancient times been generally recognized in connection with varicose disease, but have received very little attention as distinct affections. Tbe reason for tbis is twofold: First, because tbey frequently give rise to no trouble of any kind; and second, because when symptoms demanding treatment arise their existence is masked by the general varicosity wbich coexists in many cases.

Mr. Bennett (*Lancet*, April 12, 1890) describes three classes of these venous sacs and dilatations. The first and rarest form consists of a distinct sac springing from one side of a vein, with which it communicates through a small opening. This condition may or may not be associated witb a varicose condition of the surrounding veins, but some evidence of venous abnormity in the form of nævus or varix is to be found in near or distant parts. Clinically it presents the form of a softisb, compressible tumor, the connection of which with a vein may more or less easily be demonstrated. When this occurs in tbe neck tbe patient has the power, by means of holding the breath, to cause the tumor to become large and tense.

Tbe second class consists of a dilatation at the point of entry of a tributary vein into the parent vessel. In part of these cases the proximal end of the tributary and the neighboring part of the recipient are about equally involved, and in part the tributary is the more affected, and a globular swelling is produced which seems to project from the main vessel. This class seems to be almost invariably associated with varicosity of the veins in the immediate neigbborhood. Tbe tendency to dilatation seems to be congenital; its development seems to depend on the same conditions whicb promote the development of ordinary varicosity.

The third and most common class is local dilatation involving tbe wbole circumference of tbe vein. Tbis may occur in any valved vein and invariably involves the portion of tbe vein in tbe immediate neigbborhood of a valve which generally forms the distal boundary of the tumor. At first it is pyriform, afterward spherical, but rarely attains any great size. This form is often found associated with extensive varix, but it does not occur as frequently in the midst of masses of varicose veins as is sometimes supposed.

Tbe only conditions which render active treatment necessary are rapid distention causing pain and possible bæmorrhage through rupture of the cyst wall, rapid coagulation in the sac from injury, inflammation or other cause, and suppurative inflammation in dilatations packed with clot. In tbese cases the clot-packed sac should be removed togetber with the portion of the vein from which it springs. When the sac springs from a deep, important vein, like the femoral, operative treatment is contra-indicated unless tbe sac be pedunculated sufficiently to admit of ligation. When removal is impracticable in a superficial vein, division of the distal portion of the vein between two ligatures is recommended. The pain from distention may be controlled by pressure. If suppuration appear, it should be treated as an abscess, opened antiseptically and cleaned out.

Gastroschisis.—Dr. Brown (*Brit. Med. Jour.*, Jan. 4, 1890) gives the following description of a monster which breathed only once or twice:

"Tbe liver and part of tbe small intestine were projecting through the umbilical opening, whicb also admitted the insertion of two fingers. Tbe abdominal wall below the umbilicus was covered witb serous membrane only, the skin and muscle being absent from the anterior aspect of the abdomen. In both groins was a diminutive penis—without the urethra—and the scrotum. Tbere was no anal opening. Tbe legs were both abducted from arrested development and displacement of tbe pelvic bones. There was also talipes varus."

Development of the Ciliary or Motor Oculi Ganglion.—Dr. Ewart presents some investigations of the cranial nerves of sharks and skates (*Proceedings of the Royal Society*, March 6, 1890), from which it appears that tbe ciliary ganglion stands in the same relation to one of the cranial nerves, the ophthalmicus profundus, as the sympathetic ganglia of the trunk stand to the spinal nerves, and that this ganglion may henceforth be considered a sympatbetic ganglion.

The most conflicting views have for some time been held as to the origin, relations, and homology of this ganglion, whicb is known as the ciliary, motor oculi, opbthalmic, and lenticular. Some observers have confused it with the ganglion of the opbthalmicus profundus, and considered it homologous with the Casserian and other cranial ganglia, but within the past few years the ciliary ganglion and the ganglion of the ophthalmicus profundus bave been sbown to be distinct, and the old view of Arnold, that the ciliary was a sympathetic ganglion, has been revived. The researches of Dr. Ewart go to strengthen this view, and he thinks that perhaps further investigations may show tbat tbe ganglia in connection with the branches of tbe trigeminus nerve may also be considered as belonging to tbe sympathetic system. He professes to have found the vestiges of the ophthalmicus profundus ganglion in a five months' human embryo, lying under cover of the inner portion of the Casserian ganglion, and has satisfied himself that the opbtbalmicus profundus of the elasmobranch is represented in man by the nasal branch of the ophthalmic division of the fifth nerve.

Supernumerary Tonsils.—Donelan (*Brit. Med. Jour.*, May 17, 1890) reports a case in which there were two pairs of symmetrically placed tonsils. One pair was in the normal position, the other was situated low down in the pharynx. All four tonsils were hypertropbied and were removed. A microscopic examination showed that they all presented the usual characteristics seen in hypertropbied tonsils.

This case is a very unusual one in that the supernumerary tonsils were bilateral and symmetrically placed below the normal glands, from which they were separated by tbe posterior palatine fold by an interval of half an inch.

Development of the Hymen.—Scbaeffer (*Arch. für Gyn.; Am. Jour. of the Med. Sci.*, June 1890) bas made a careful study of tbis subject, based upon the examination of the genitalia in nearly two hundred fœtuses. He found tbat in every instance the hymen, as early as the fifth month, was composed of two lamellæ, the inner being derived from tbe vagina, the outer from the folding in of the vulva; in many cases the two layers coalesced, but tbey sometimes remained distinct until birth, tbougb seldom later. Tbe fœtal hymen bad on its inner (upper) surface transverse folds similar to tbose in the vagina; between the folds small pockets were often formed, from which cysts of tbe hymen might form. Certain anomalies in the hymen—the hymen crenelatus, dentatus, carinatus, falciformis, etc.—may be accounted for by irregularities in the distribution of tbese folds. On tbe outer surface of the fœtal hymen numerous folds were found, wbich extended from the fossa navicularis, nymphæ, clitoris, and meatus. Tbe writer gives this summary of the arguments in favor of the bilamellar origin of the hymen: 1. In over one fourtb of the specimens the lamellæ were clearly demonstrated. 2. Tbe outer lamella was proved to be developed from the folds which radiated from the region of the vestibule. 3. Various stages in the union of the two lamellæ were observed. 4. The outer lamella had tbe same color and epithelial covering as the vestibule, tbe inner that of the vaginal mucosa.

The Nerves of the Back of the Hand.—Zander (*Fortschritte der Medicin*, No. 9, 1890) gives these results of his investigations:

Tbe dorsal finger anastomosis supplies not only the nail of the tbumb, but also of the little finger, occasionally of the fore and ring fingers, and rarely of the middle finger. Tbere is an interchange of filaments between tbe anastomoses on the dorsal and volar surfaces of tbe fingers, and wherever tbe dorsal nerves fail to supply the nail the palmar nerves supply the deficiency.

Upon the back of the hand proper tbe areas of distribution of the radial and ulnar are not sharply divided along tbe middle line, but the branches of each nerve anastomose with those of tbe other. Frequently tbe skin of the entire dorsal surface of the hand is supplied by both nerves, and it is quite common that the middle portion is supplied with sensitive filaments from botb sources. On the ground of this observation it can be affirmed, in cases where section of one of these nerves has produced no marked loss of sensibility, that a very

extensive interchange of the nerve fibers exists; the less extensive this is, the more clearly will the loss of sensibility appear.

But the integument of the dorsum of the hand receives its nerves of sensation not only from the superficial branch of the radial and the dorsal branch of the ulnar, but also from other sources. The musculo-cutaneous unites with the radial and innervates the integument of the thumb and the radial part of the back of the hand. The posterior inferior cutaneous nerve the writer has found in several cases to supply the entire middle part of the back of the hand. Turner once saw the external interosseous branch of the radial continue to the fingers, and innervate the adjacent sides of the fore and middle fingers. A more important source of innervation is found in the anastomosis between the dorsal branch of the ulnar and the median cutaneous. Twigs from the palmar nerves also rise between the fingers and spread over the neighboring surfaces.

On account of these facts Zander maintains that in any given case it is very difficult, if not impossible, to diagnosticate the section of the involved nerve trunk by means of the degree and extent of loss of sensation on the dorsal surface of the hand.

Miscellany.

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for August 15th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—										
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.
New York, N. Y.	Aug. 9.	1,636,598	815	..	..	..	..	..	..	8	4	12	10	13

The Treatment of Cystitis in Women.—Dr. T. M. Madden presented the following note at the recent International Medical Congress:

Of all the diseases which come before us in gynæcological practice there is none more frequently met with, more distressing in its effects, or more intractable to the means generally relied on for its relief than cystitis in women. I therefore desire to bring under the notice of the International Medical Congress a method of treatment which I have found, by clinical experience, to be generally successful in the rapid curative treatment of this condition. The measures most commonly employed in such cases are merely palliative, and may relieve, but *per se* can never cure, well-established cystitis in women. Nor am I aware of any method by which that can be accomplished save by giving the bladder absolute physicological rest. For this purpose Dr. Emmet's operation—*i. e.*, the establishment of an artificial vesico-vaginal fistula—may be successfully employed in some instances, but the practical objections to it are so great and obvious that for several years past I have abandoned this procedure in favor of another which I have found more generally effectual and quite free from the disadvantages of the operation referred to. The plan which I have now employed in a very large number of cases of cystitis in the gynæcological wards of the Mater Misericordiæ Hospital, Dublin, consists firstly in the full dilatation of the uretheral canal with the instrument exhibited, so as to paralyze the contractility of the sphincter vesicæ, and thus produce a temporary incontinence of urine; and, secondly, in the direct application through the same instrument of glycerin of carbolic acid to the diseased endovesical mucous membrane. I may add that any pain thus caused may be prevented by the previous topical application of a solution of cocaine, and that the procedure recommended seldom requires to be repeated more than once or twice at intervals of a week or ten days; and, combined with the internal use of boric acid, rarely fails to effect a rapid cure in any ordinary case of cystitis.

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

CLINICAL LECTURES
ON SOME COMMONLY OBSERVED FORMS OF PULMONARY DISEASE.

DELIVERED AT
THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

By JAMES K. CROOK, M. D.,
INSTRUCTOR IN CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS, ETC.

Lecture I.

Simple Acute and Chronic Bronchitis of the Larger Tubes.—This morning, gentlemen, we have a number of cases representing the most common form of disease of the respiratory organs, viz., inflammation involving the larger bronchial tubes. Fully two thirds of all the cases observed at our chest clinics are of this nature, and you will find it a very frequent affection in almost every part of the temperate zone the world over. We will examine these cases *seriatim*, and endeavor to learn what features of interest they present. No. 1 is that of a young man, aged twenty-four, by occupation a truck-driver. He informs us that he received a severe wetting, while engaged in his work, three days ago. On the following morning he experienced some chilly sensations, with a sense of malaise and lassitude, and during the day was seized with a harsh, painful, dry cough. He also felt a sensation of oppression and obtuse pain and rawness in the front of his chest, more particularly behind the breast bone. All these symptoms he has this morning, but now a small quantity of glairy mucus is raised occasionally, and he also feels sensations of soreness and pain along the false ribs. These are undoubtedly due to the severe muscular contractions caused by the coughing efforts. We find his temperature to be 99·5° F., and his pulse rate 94 to the minute. A careful physical examination reveals no physical signs whatever save a slight sibilance of the inspiratory and expiratory notes. We are thus led to a plain and unequivocal diagnosis of simple acute bronchitis in the first or dry stage. To use a lay expression, our patient has caught a "bad cold." We base this diagnosis on the history of the case, and on the absence of all signs or symptoms of other pulmonary troubles. There is no pain in the side, no high temperature, no dullness on percussion, and no bronchial breathing. No portion of the lung is withdrawn from the exercise of its function. The signs are negative, and that is what we expect to find in almost every case of simple acute bronchitis in the first stage, unless the attack is exceptionally severe, when we may have harsh breathing or sonorous and sibilant râles. The pathological basis of this patient's trouble consists at this time simply in a certain amount of reddening and tumefaction of the mucous membrane of the primary bronchi, and probably of the nasal passages and trachea. The membrane is very dry and irritable. There is probably also more or less hyperæmia and perhaps inflammation of the bronchial glands. The prognosis is good. Our patient is young and strong, and, with proper care, ought to be well in a few days. If he were a weak and puny subject, or else a little child, or an old person above sixty, we would be more guarded in the prognosis. In such cases the disease is liable to dangerous sequelæ, as we shall see in referring to chronic bronchitis. The indications for treatment here are: 1, to observe care against further exposure, as in sitting in a draft, going suddenly from a warm to a cold atmosphere, wearing insufficient clothing, etc.; 2, to relieve the irritable cough and the soreness and oppression of which he complains. The disease is not so far advanced but that we may still hope to abort it. For this purpose I am in favor of the old-fashioned treatment of a strong mustard foot-bath at bedtime. The feet and legs should be bathed up to the knees, and should remain in the hot water at least ten minutes. They must then be wiped dry with a coarse towel, and the patient must go to bed at once. He should then take a powder consisting of one grain each of ipecac and opium and ten grains of antipyrine. This formula is similar to the time-honored Dover's powder, except that the sulphate of potassium is replaced by antipyrine. I have never been able to see the value of the sulphate of potassium in the Dover's powder, while I am well convinced of the good effects of the antipyrine. This dose will cause profuse diaphoresis, but is quite sure to give the patient a good night's rest, free from coughing. A vigorous friction of the chest with the hartshorn or soap liniment will aid its action. To-morrow morning on rising he should take a good saline purgative in the shape of a glass of Villacabras or Rubinat mineral water, or a couple of heaping teaspoonfuls of Sprudel salt. By this treatment we may reasonably expect a modification of his symptoms, possibly a complete cessation. It will at least greatly ameliorate the severity of the trouble. However, there is apt to be more or less bronchial irritation and cough for several days, which may be severe enough to require treatment. Our object will then be to promote the secretion of the bronchial membrane so as to allay the dryness and irritation which produce the cough. Our subsequent measures need not be specially active, as the tendency of the trouble is toward recovery. Probably ninety-five per cent. of cases in such subjects as this young man would end in recovery without treatment. To hasten this end, and to promote his comfort, we should prescribe a mild, stimulating expectorant. There are a large number of these remedies, but I know of none more reliable than the chloride of ammonium. It has been justly said, however, that this compound, when mixed with a syrup, is not pleasing to the palate. To obviate this bad taste, and also to gain the benefit of its sedative action, I have been in the habit of adding the spirit of chloroform, a favorite formula being as follows:

℞ Ammon. chlorid. ..... ʒ ij;
Spt. chloroform.,
Tinct. opii camph.,
Syr. ipecac., } ..... āā f ʒ iij;
Syr. tolut. vel syr. prun. virginian.... ad f ℥ iij.

M. Sig.: Dose, a teaspoonful as required.

This is not a bad-tasting mixture, and I have found few

people object to it. A little chloride of apomorphine (one fifteenth to one sixth of a grain two or three times a day) is sometimes equally efficacious.

Patient No. 2 is a man aged thirty, who is in the second stage of bronchitis. His case might be called subacute, as his symptoms have been very mild from the beginning, about ten days ago. He is taking the formula I have mentioned. He says he needs only a little, and takes half a teaspoonful on retiring and on rising in the morning. The cough is loose and not at all irritating. The expectoration has been quite copious for several days, but is now becoming less. It is rather thick, and composed mostly of mucus, with a little pus. During the first two or three days he observed an occasional streak of blood, but this was not an alarming occurrence, as it is quite common in the first stage of bronchitis. The lining membrane of the bronchi is now moist, and probably only a little congested. We need not subject this patient to needless precautionary measures. He is doing well now, and with ordinary care will recover his health in a few days.

Patient No. 3, however, shows us that all cases do not progress so favorably. He is a tailor, forty years of age, and of a rather delicate physique. Early in January (about six months since) he fell a victim to the morbific atmospheric influences prevailing at that time, from the effects of which he has never recovered. After a week or two of sneezing, headache, pain in the back, rigors, etc., he settled down to a steady cough, which has not left him since. But he has developed other symptoms which somewhat augment the gravity of the case. His appetite has failed and he is losing flesh lately; he also finds himself somewhat short of breath on exertion. He complains of irregular thoracic pains and there is some tenderness on pressure at different parts of the chest. The cough is attended by a profuse greenish-yellow expectoration, which at times is very viscid and tenacious and hard to get up. Occasionally, but especially early in the morning on rising, he gets a coughing spell which lasts for ten or fifteen minutes, and even leads to violent retching and vomiting. These spells almost always set up a severe headache. The patient has taken several remedies from time to time, but they do not seem to have helped him much. On physical examination, we find all the methods to yield negative results, except percussion and auscultation. On percussion, in the lower and posterior parts of the lungs we find a certain degree of dullness on both sides. In these same regions, on auscultation, we find an abundance of large and small moist râles. These physical signs are undoubtedly due to a gravitation of the fluid secretions of the bronchial tubes to the dependent portions of the lungs. Higher up we still find râles, but they are more dry in character, being chiefly sibilant and sonorous. There is no circumscribed area of dullness or bronchial breathing. We need feel no hesitation in pronouncing this a case of chronic bronchitis. There are not sufficient elements in the history or physical signs to warrant any other conclusion. If we could see the lining of the bronchi, we should find less hyperæmia and tumefaction than in Case I. The membrane is probably of a bluish-red tint, or it may be slate-colored or grayish. There is, no doubt, an abundance of mucus, and probably pus, covering the membrane in places, which gives rise to the dyspnœa of which he complains. There are elements of gravity in this case which did not exist in the others. The patient is already considerably run down and he is progressively getting worse, and the disease may wear him out by its very obstinacy. Asthma and emphysema are always to be feared in such cases; but, worse still, the inflammation may descend into the smaller bronchi, giving rise to bronchiolitis or the so-called capillary bronchitis, and eventually to collapse of the pulmonary alveoli and lobular pneumonia. Such terminations of bronchitis are not uncommon in infants and old persons, but they also occur in debilitated persons of adult or middle life. There is even a possibility that the persistent bronchial inflammation may light up a latent tuberculosis. We can thus see that we have a case of great importance on our hands. Should he escape the foregoing evils, the disease may still continue for years and lead to bronchiectasis from loss of elasticity of the bronchial walls. We hope for a more favorable termination, however, and with proper management ought to be able to achieve it.

The indications for treatment here are clearly of the tonic and supportive order. We should regulate the patient's daily habits and regimen. He should wear warm flannels next his skin and avoid undue exposure. However, on all pleasant days, he should spend as much time as possible out of doors. Moderate stimulation is advisable to sustain his strength. If the patient can afford it, he may take a glass or two of claret with his meals, and the latter should be composed of as nourishing food as possible, especially meats and farinaceous articles of diet. We may find it necessary to administer a bitter tonic for his appetite, and for this purpose I know of nothing superior to the old-fashioned formula known as Smith's bitters, consisting of half a drachm each of the compound tinctures of gentian and cinchona, a dose to be taken fifteen or twenty minutes before meals in a little water. We can be reasonably sure that a little good exercise in the afternoon, with a dose of this preparation, will give him a good appetite for his dinner. It would not be a bad plan to administer also a drachm of Fellows's hypophosphites after each meal and at bedtime. A stimulating expectorant is clearly indicated. We wish to keep the products of bronchial exudation in as fluid a state as possible, so as to admit of their ready expulsion. The formula recommended in the case of acute bronchitis would be useful, but as there is considerable adynamia here, I would replace the chloride with the carbonate of ammonium. The addition of a few grains of the iodide of potassium would also increase its efficiency. But we can not undertake to enumerate the many remedies which have been found useful in bronchitis. The last edition of the *National Dispensatory* gives a list of more than one hundred and twenty. We can only say that, whatever remedy we choose for the cough symptoms, we should give as little of and at as long intervals as is consistent with the patient's comfort. The remedy will probably have to be administered for a long time, and such drugs are very apt to upset the appetite and digestion. I have very little faith

in local measures in the treatment of chronic bronchitis, and rarely employ them. If our patient were in a position to afford the expense, we should advise him to get away from the seaboard for a while at this season (summer), and spend a few weeks in the Catskill or Adirondack Mountains.

Original Communications.

STUDIES IN THERAPEUTICS.
ASSAYED GALENICAL PREPARATIONS.

By JOHN AULDE, M. D.,
PHILADELPHIA,
MEMBER OF THE AMERICAN MEDICAL ASSOCIATION,
OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA, ETC.

Soon after the publication of my lectures upon The Clinical Applications of Drugs, which appeared in this Journal during the month of April last, I received a number of communications asking for further information upon various topics; but the question which I deemed of greatest importance was in regard to the assayed fluid extracts mentioned. Those who read the lectures will remember that I insisted upon the need of giving attention to the character of the fluid extracts employed, and I desire again to emphasize that need, and to point out that such preparations are in many instances superior to alkaloids in the treatment of disease.

To some, the foregoing statement may appear absurd, but a few words will suffice to show that the position is well taken. It is well known among clinicians that many galenical preparations are not truly represented by the alkaloids they contain; but we depend upon the presence of the alkaloid for the activity of the drug, as without it our therapeutical applications must be to a great extent tentative. No better illustration of this point can be given than in the use of cinchona. There are times when the salts of the alkaloids will answer our purpose admirably, but at other times an infusion will do as well; then, again, it becomes necessary, in order to obtain all the virtues of the bark, to employ the extract. Occasionally it has been found that the combination of one or more of the salts with the fluid extract will act more efficiently than either of these preparations alone. It must be borne in mind, however, that these conclusions were determined upon at a time when less care was given to the manufacture of fluid extracts than is given at present, and there can be no doubt in the minds of practical pharmacists that fluid extracts were often prepared from inferior qualities of bark. It is not reasonable to suppose that inexperienced young men are competent to select and pass upon the quality of a product so simple as Peruvian bark; and if there is difficulty here, what must be the dilemma of those who have to decide upon the character of crude drugs where great experience is required, owing to their peculiar delicacy and liability to sophistication? Plants like aconite, cannabis indica, digitalis, and gelsemium require experienced operators to determine the true from the false; but in addition, they demand the skill of the chemist to ascertain the presence of the proper proportion of active constituents. *Chemical analysis* alone serves to demonstrate their value, just as an assay process determines the presence and percentage of precious metals, and enables the purchaser to set a proper value upon the ore which is offered for sale.

The advantages of assayed galenical preparations must be apparent to the most obtuse observer; if not from the foregoing remarks, his own experience has convinced him that certain preparations are better than others, owing to their certainty of physiological action. The committee now engaged in a revision of the United States Pharmacopœia will doubtless be guided to the conclusion that the advance of scientific medicine and the success of the practitioner alike depend upon the early adoption of processes for the determination of the active constituents of all galenical preparations, where those constituents occur in the form of an alkaloid, a glucoside, or a neutral substance. Until such rules become obligatory upon the pharmacist, the work of the physician must to a great extent be a matter of guesswork; otherwise, the results which he desires from the exhibition of certain drugs of this class, when they are as expected, will be mere accidents, and in general anything but mathematically exact.

The rapid advances in other departments of science are sufficient to warrant us in insisting that the noble science of medicine shall not lag behind. The progressive spirit of the nineteenth century invites the medical man to take a step in advance, just as it has brought the surgeon from the darkness of ignorance and superstition into the light of truth and opened a new era in this department of medical science. Let this be the beacon which shall guide us to an advanced position in the use of drugs. Possessing medicaments which are exact and reliable in alkaloidal strength, the physician will attain greater skill in their administration, and the temptation to make combinations will gradually disappear. Too often combinations mean ignorance on the part of the practitioner, and unfortunately they are used at the expense of the patients' strength.

No physician can fail to appreciate the benefits which must accrue to his patients through the influence of reliable medicines. When called to see a patient in a distant country town, the first inquiry of the physician should be in regard to the reliability of the druggist; and when prescribing for a patient in a dilapidated portion of a large city, he should be particular to instruct his patient as to the druggist he ought to patronize. Happily, his selfish disposition and the welfare of his patient run in parallel lines. So long as the patient remains in bed, the doctor knows that his professional ability is not very highly rated; and besides, when the patient again goes on the street, he becomes at once a moving and talking monument of the professional skill of his physician; the *éclat* which follows a rapid recovery of an exceptionally interesting or exceptionally prominent patient is more to the physician than great riches. For these reasons, if not for those higher and holier motives which prompt men to face death for their fellow-men in times of sickness, the doctor is prompted to seek remedies that he can depend upon in the hour of need.

The objections urged against the plan suggested are not so formidable as its opponents would have us believe, nor are they insuperable. They are such as serve to break the force of the arguments against the method proposed, because they show beyond question the fallacy of the premises, and prove the uselessness of a system which is inefficient because of its irregularities. The opposition comes from sources least suspected, and, owing to the under-current of antagonism, the necessities of the physician must be more strenuously insisted upon than the overwhelming evidence in its favor would appear to require.

For example, it is alleged that no pharmacist of ordinary ability is capable of undertaking these delicate operations, and it is said also that, had he the capacity, it would require too much time and an unnecessary outlay for apparatus; but these are flimsy excuses where life is at stake. On the contrary, it is stated on the authority of Professor Mew, of Washington, D. C., analytical chemist to the purveying department, U. S. Army, that any well-qualified druggist can, in the course of a few weeks, be thoroughly educated to do this work, and that the expenses of the outfit are comparatively trifling when compared with the increased advantages which would attend the introduction of assayed products. Again, it has been suggested that it would be an easy matter to prepare a finished product which would meet all the requirements in respect to alkaloidal strength by any known chemical process, through the addition of foreign substances which possess no medicinal value whatever; but, as no reputable pharmacist would be guilty of such sophistication, only a short time would elapse before the source of the spurious preparations would be discovered. The notion that such counterfeits could be placed in the hands of an innocent druggist, who should be held responsible unless he could show the preparation in the original package, is too absurd to be entertained for a moment.

Finally, it is strongly urged that if we are coming to alkaloidal therapy, it would be far better to discard the other products entirely; but there are several valid reasons why this plan can not be adopted at the present time. First, the physiological actions of alkaloids in many instances are not fully understood; consequently, further investigation is required. Secondly, quite a number of alkaloids do not, as previously stated, represent the physiological action of the crude drug, owing to the presence of principles which neutralize one another; while some alkaloids, like cannabine, are too expensive even for physiological investigation. Possibly they may in the future be produced synthetically at a cost low enough to permit their general employment. Some alkaloids, such as those belonging to the *Solanaceæ*, can not be used continuously for any length of time, owing to their tendency to accumulate in the liver and obstruct its functions. While admitting that many of the active principles of vegetable origin are used with satisfaction, and that there is no doubt of their safety, I must insist that such usage can have no direct bearing upon the question, where these principles do not represent the physiological actions of the crude drug, or where they can not be produced in such quantity, and at an outlay which will enable their use to become general.

Clinical experience is, therefore, the final and crucial test which must guide us in determining whether or not we are to use galenical preparations which have been submitted to an assay process. Those opposed to the method must be regarded as opposed to progress; they are entitled to be classed with a large number of physicians, now passing from the stage, who knew but little of the possibilities of drugs from a scientific standpoint, who practiced wholly on an empirical basis, firing shot-gun prescriptions into their patients from day to day.

We are not in a position to estimate with any degree of accuracy what a great blessing physiological investigation has been to mankind, nor can we appreciate how human life has been prolonged through this apparently insignificant agency; but the time is approaching when the practice of physic will be conducted upon a surer footing, when the physician will be able to calculate with a reasonable degree of certainty the effect which any particular drug will produce; and he can give the nurse instructions which will enable her to discontinue one preparation and replace it by another at the proper time, just as we do now in controlling the temperature and pulse in typhoid, scarlatina, and in acute forms of disease. The stepping stone toward accomplishing this achievement is to be found in the use of galenical preparations made to conform to a regulated standard of alkaloidal strength.

Almost daily-recurring incidents might be recorded which illustrate the truth of the propositions here advanced, but a few will be quite sufficient. Some time ago, a professional friend complained to me that, even when following my directions to the letter, he could get no satisfactory results from the use of cannabis indica for the relief of supra-orbital neuralgia and certain forms of dysmenorrhœa. When asked whose manufacture of the drug he had employed, he could not tell. I advised him to use the so-called "normal liquid," and since that time the treatment of these affections, where this drug was indicated, has been invariably successful. Quite recently I read some suggestions regarding the use of gelsemium in the form of a fluid extract, the dose being given at from ten to twenty drops, and came to the conclusion that the preparation used in this manner must be practically inert, and that a teaspoonful might be taken with safety. With the use of "normal liquid" gelsemium the cases are rare indeed where ptosis can not be produced in two hours by the judicious employment of ten drops. Within the past few weeks I had, with an exceptionally practical and reliable druggist, a conversation which turned upon the subject of ergot. Taking down the shelf-bottle, I pointed to a precipitate in the form of a poultice, when he informed me that it was impossible to keep this preparation any length of time without precipitation. Personal observation enables me to contradict this statement, as I have kept for more than a year a small bottle of the normal liquid, and there are no indications of a precipitate.

About two months ago a physician wrote me that he had used rhus toxicodendron, in both large and small doses, in nearly all the disorders for which I had recommended it, and had utterly failed to notice any result whatever, but,

like my friend with the cannabis indica, he did not know whether the preparation used was the fluid extract made from the dried leaves or the tincture made from the fresh leaves growing in the shade and gathered during the period of efflorescence. A sample which I immediately sent him relieved in every case, including a rheumatic trouble from which he had long suffered himself, and he was therefore prepared to champion the drug. This preparation, it should be remembered, is one which depends for its activity upon the presence of a volatile substance, toxicodendric acid, and the subject is introduced here as an illustration of the facts already pointed out—viz., that the preparation of drugs for the relief of disease can not receive too much care. It shows, too, that drugs, to be efficient, must be prepared according to certain recognized methods; hence it is extremely doubtful if in their preparation inexperienced clerks can be depended upon.

Both aconite and belladonna are drugs which are extensively used in general practice, but, as usually found in the shops, they are the most uncertain of all in the Pharmacopœia, with the possible exception of the tincture of opium. The first of these is a remedy of prime importance in the early stages of all inflammatory affections in which mucous surfaces are involved, and the failure to obtain promptly the physiological effects of the drug means an attack of pneumonia, amygdalitis, or other serious disorder. The physician prescribing this drug especially desires a reliable preparation, because, after the first twenty-four hours, when his patient is seen on the second day, the period for its administration may have passed, when efforts must be made to conduct the disease to a favorable termination rather than control it. With the exhibition of reliable preparations, attacks of this character in the acute stage may frequently be aborted.

What is true of aconite is notably applicable to preparations of ergot. With his hand upon the uncontracted uterus, when every throb of the heart means a gush of blood which may possibly be the last, when the vision fails, and the recently delivered woman raises a feeble but piercing cry that she is dying, then it is that the physician thinks of the quality of his ergot. It is his sheet-anchor. The movements of the nurse in procuring it may be slow, the patient may hesitate, but the physician knows that, if once the drug is taken, the danger is averted. There are other instances in which the necessity for reliable medication is quite as great, and, when those who oppose the method assert that such work as I have suggested is unnecessary because it takes too much time, that it will require the pharmacist to increase his stock of intelligence and increase by a few dollars his outlay for apparatus, I most respectfully submit that it is a sad commentary upon the boasts we are accustomed to make regarding our modern civilization.

In conclusion, therefore, I desire to offer my plea for the employment of assayed galenical preparations, and, as the normal liquids have served me well, I commend them to the attention of my brethren in the field, believing that they will be instrumental in guiding them to a more scientific use of drugs. By their use for several years past I have been able to conduct the administration of medicines with greater precision, and at the same time have learned to employ drugs of this class with due regard to their physiological actions. As a consequence it seems to me that my medical horizon has gradually widened, and, as my knowledge of diseased conditions increases, my respect for drugs improves. As a result of clinical observation, I recommend the use of small doses, because the small doses, given at short intervals, at least in acute cases, more quickly bring the disease under the control of the physician, while, with medicines which are unreliable, the results are always uncertain. If the attendant is interested in prolonging the patient's illness, haphazard medicaments are a desideratum; but if he desires the recovery of the patient, and possesses selfish motives which prompt him to add laurels to his professional reputation, the remedies which have been submitted to a chemical or physiological test to determine their activity are the only ones he will be willing to accept.

It would be interesting to say a word in regard to the precautions to be observed in the preparation of assayed galenical products, but it is believed that enough has been said to establish a good case, as the evidence is substantial and complete.

1910 Arch Street.

THE LARYNGOLOGY OF TROUSSEAU AND HORACE GREEN.

*AN HISTORICAL REVIEW.**

By FRANK DONALDSON, M. D.,
BALTIMORE.

Nearly all the prominent and valuable discoveries in science and the arts have reached completion gradually. Thoughtful minds at different epochs have been occupied with attempts to overcome the same difficulties and to solve identical problems. Not aware how near they have been sometimes to success in their attempts, they have often abandoned their work when perseverance would have rewarded them with brilliant results.

We are all familiar with the history of the discovery of the little instrument which has furnished us with a name as well as a science and a practical, invaluable art. Starting from the middle of the last century (1743) with the ingenious device of M. Levret, the laryngoscope had nearly been reached several times by Bozzini, by Senn, and others, but never so nearly as by Babington in 1829. It was left for Garcia, in 1854, to demonstrate in his own person autolaryngoscopy, and to present to the profession his simple mirror and reflector enabling all to illuminate and inspect the hitherto darkened chambers of the larynx and nares.

The imperfect and unsatisfactory art of laryngology yielded to the exact science of laryngoscopy.

The feat was accomplished. When once the discovery had been made, there was no difficulty in the future.

The history of the invention and of the futile preceding efforts it is unnecessary to mention.

The object of this brief paper is to inquire into that period of the history of laryngology immediately anterior

* Read before the American Laryngological Association at its twelfth annual congress.

to Garcia's successful inspection of the larynx, and more particularly of the part played by Trousseau, of Paris, and by Horace Green, of New York. The French give great credit to the former, and the American has had his appreciative friends and also his detractors. I thought it might not be uninteresting to endeavor to take an impartial view of both, the writer having had as a student the privilege of following Trousseau in 1850–'51, and of closely watching his practice. All acknowledge that he was a very able clinician. He was particularly interested in the study of diseases of the mouth, oro-pharynx, and larynx—all of which are generally included in the designation of laryngology. His wards contributed abundant material for lectures upon common membranous sore throat, gangrenous and inflammatory pharyngitis, diphtheria, and tubercular laryngitis.

Trousseau popularized the operation of tracheotomy for membranous croup, which he regarded in many cases as diphtheritic. He was very successful. He insisted that the operation should be performed early in the disease, and he used strong solutions of nitrate of silver freely in the orifice after opening the trachea.

His limited knowledge of the pathology of the larynx was that of his day. He taught his classes that tuberculosis and syphilis were the almost exclusive causes of aphonia and dysphonia. For these his treatment was by the application of nitrate of silver in the form of the solid stick to the pharynx, or by solution injected through perforated silver curved tubes passed behind the epiglottis. The shower from these was thrown over the epiglottis and the supraglottis. If it touched any diseased points, it also irritated the healthy surfaces. The oro-pharynx was really the only part that he could illuminate sufficiently to be able to apply the medicaments accurately. The diseases of the upper pharynx and posterior nares he overlooked, for the rhinoscope had not then been applied. These were the points of his practice in 1850 in connection with laryngology. A set of silver tubes I brought home with me, and used for some years as I had seen him apply them, but I soon ceased to use them, as they were unsatisfactory.

Let us for a moment see what Trousseau did after the laryngoscope had been used by others.

In the last edition of Trousseau's *Clinical Medicine*, published in 1867, edited by M. Michel Peter, his pupil, and translated by Sir John Rose Cormack and Bazire, it is maintained that Trousseau and Belloc, long before the publication of their work on laryngeal phthisis (in 1837), felt that the examination of the larynx by a suitable speculum was a likely means of attaining accurate diagnosis; further, that at the date of their publication they were occupied with the construction of such a speculum laryngis. At that time, likewise, M. Sellique, an ingenious mechanic, who was also a sufferer from laryngeal phthisis, made for his physician an apparatus consisting of two tubes—one for throwing light on the glottis, and the other for affording a view of the image of the glottis, as reflected in a mirror placed at the guttural extremity of the instrument. There were serious defects in this instrument; we are told that the difficulties in applying it were so great that Trousseau ceased to try to use it. It is a curious fact that neither Trousseau nor others took any notice of an instrument proposed and presented in 1825 to the Institute by M. Caguiard de Latour, especially as Fournié affirms that it was the first discovery of the laryngoscope. It consisted of a small mirror, which was to be introduced into the fauces and, by the aid of another as a reflector, to catch the solar rays and reflect them and illuminate the epiglottis and the glottis. Its practical application allowed only the inspection of the epiglottis. M. Latour lacked perseverance, or he might have been the successful discoverer. Benniti, of Paris, in 1832, had asserted his ability to see the vocal cords with Sellique's instrument—his double-tubed speculum, of which one tube served to carry the light to the glottis, and the other to bring back the image to the eye. Trousseau discredited this statement, and undertook, in his work on laryngeal phthisis, to prove that the epiglottis formed an insuperable impediment to a view of the interior of the larynx. Trousseau's rejection of Sellique's and Benniti's instruments, by the weight of his name and position, was calculated to defer the discovery of the laryngoscope.

In his clinic on œdema of the larynx, as reported in the last edition, Trousseau, or his editor, says: "The laryngoscope has been carefully studied in England and Germany; when it has attained a greater degree of perfection it will, no doubt, render service not only in the diagnosis, but also in the treatment, of laryngeal affections."

If he were living, how cordially should we welcome him to witness the perfection its application has reached! He would be as dazed as Rip Van Winkle was when he awoke from his prolonged sleep.

Dr. Horace Green, as a very young man, was impressed, in several cases of follicular disease of the throat in which he had become interested, with the uncertainty attending their treatment. He went abroad to visit the hospitals of Europe to see if there had been any discoveries in connection with the pathology and treatment of the diseases of the larynx and the adjacent organs. In a casual conversation he had with Dr. James Johnson, the editor of the *British and Foreign Medical Review*, in alluding to the difficulties and uncertainty which attended the treatment of laryngeal disease, Dr. Johnson intimated that all modes of treatment would fail us until appropriate therapeutic agents could be applied directly to the lining membrane. This remark, in connection with Green's past experience of the nature of the disease, and especially of its local character, made an abiding impression on his mind, and suggested the idea of the possibility of medicating the cavity of the larynx by catheterization. This was in 1838.

He made for himself a probang, with which he commenced introducing a solution of nitrate of silver into the pharynx and into the larynx. He found at first some difficulty, but he gradually made himself very expert in catheterizing the larynx and the bronchi. He met with such success that he soon made a reputation and enjoyed an increasingly large practice.

His first work was a treatise on *Bronchitis*, published in 1846. In this he advocated strongly, amidst much opposition, topical applications of nitrate of silver to the interior of the larynx and catheterization. He gave numerous cases

where he had succeeded. These were in addition to the cases previously, in 1841, reported to the Medical and Surgical Society of New York. A committee of this society, appointed in 1847, condemned his practice. The members repeatedly and publicly denied the possibility of cauterizing the interior of the larynx. Why is it that there are always persons who are persistently incredulous and cavil at new things?

A resolution was offered asking Dr. Green to withdraw from the society. His offense was that he had repeatedly performed an operation which even a professor of anatomy declared impossible, although accidentally in many cases particles of food, besides bits of coin and other foreign bodies, had passed unhindered through the glottis. Others accused Dr. Green of imitating Trousseau and Belloc. Dr. Green warmly defended himself against the charge of having imitated Trousseau and Belloc. He stated that he had commenced his method of cauterizing two years before he knew of the writings of Trousseau and Belloc. He admitted that to them belonged the credit of having been the first to prescribe and employ topical medication in chronic diseases of the larynx. He maintained that he was the first to pass a sponge-probang loaded with a strong solution of nitrate of silver below the epiglottis, through the larynx and rima glottis, down into the trachea, thus reaching disease of these parts with more certainty.

Trousseau's method was to saturate the sponge with the solution of nitrate of silver; next, the mouth being open, to depress the tongue with the handle of a spoon and introduce the porte-caustique. As it is passed over the isthmus of the gullet, it produces an effort of deglutition which raises the larynx. This moment is seized upon for bringing forward the sponge, which, in the first part of the operation, had been carried to the entrance of the œsophagus. By this means he reached the opening of the larynx by elevating the epiglottis; and then, by pressure, it was easy to pass the caustic solution into the larynx. Dr. Green deserves the honor of having been the first to persist in this treatment, and practically he was the inventor, but he was not the discoverer. Sir Charles Bell made applications of caustic to the respiratory mucous membrane as early as 1816. In his work, *Surgical Observations*, will be found a record of these cases. In one case of extensive ulcerations of the glottis he says: "I made a small pad of lint, and attached it to the ring of a catheter wire after bending it so as to pass it over the tongue and epiglottis. I dipped the lint in a twenty-grain solution of caustic, and touched the glottis with it in this manner: With the finger of my hand I pressed down the tongue and stretched the forefinger over the epiglottis; then directing the wire along my finger, I removed the point of my finger from the glottis, introduced the pad of lint into the opening, and pressed it with my finger."

This treatment was considered hazardous and was abandoned. Mr. Vance, a naval surgeon of eminence, was in the habit of employing topically a solution of nitrate of silver in the treatment of laryngeal diseases. Dr. Stokes mentions Mr. Cusack as having introduced nitrate of silver by saturating a piece of lint sewed on the end of his index finger; by these means the solution was carried with great facility to parts of the pharynx and even to the rima. Trousseau contends that his master, Bretonneau, as early as 1818, carried over the arytæno-epiglottic ligaments a sponge wet with lunar caustic to the entrance of the larynx; yet Trousseau denied that Dr. Green or any one else could introduce instruments below the vocal cords; indeed, he maintained that the operation was impossible.

Dr. Green lived to see the best men abroad and in this country candidly admit that he had done as he reported that he had. Dr. Cotton, Dr. Hughes Bennett, Dr. Fordyce Barker, Dr. Sayre, Dr. Carnochan, Dr. Sims, Dr. Praslee Davis, Dr. Bowditch, of Boston, and Professor Davis, of the University of Virginia, had seen Dr. Green demonstrate the entrance of instruments into the larynx and trachea. They had all seen the passage of air coming through the catheter blow out the candle. Dr. Sayre, always fearless and truthful, so testified before the New York Academy of Medicine. An overwhelming demonstration was made at the request of Dr. Carnochan. Dr. Green introduced the probang through the larynx of a man who had attempted suicide by cutting his throat, and in whom the orifice in the trachea had never healed. Dr. Green passed the probang until it made its appearance at the opening in the trachea. This proved that there was no anatomical impossibility, as Trousseau had contended, of catheterism of the larynx.

Dr. Green wrote vigorously on the *Local Origin of Constitutional Diseases*, the converse of Mr. Abernethy's work on the *Constitutional Origin of Local Disease*. He advocated topical medication as of vast importance. This showed his independence of thought and his boldness in expressing his views at a period in the history of medicine when there existed such superstitious over-confidence in drugs administered internally for all the ills of life. He cared not for the unpopularity of thus combating polypharmacy. He had, it must be admitted, too implicit faith in the topical application of his favorite local application—nitrate of silver—for follicular disease, croup, spasmodic asthma, laryngitis, chronic bronchitis, and other diseases of the respiratory organs.

Dr. Green's work on *Polypi of the Larynx and Œdema of the Glottis* (1859) shows that the thoughtful observation of the author was turned toward the interior of the larynx, and that he was not to be led by traditional teaching, either in his views of laryngeal pathology or in his practice. Dr. Green did not hesitate to express the opinion, and to leave it for future experience to confirm or invalidate, that foreign growths occurred in the opening of the air-passages in many instances where their presence was neither suspected nor discovered; and that, if the attention of the profession should by any means be directed to this subject, it would be found that the existence of polypi and other excrescences in these passages was an occurrence much more frequent than had been supposed. On this point of pathology Dr. Green was far in advance of his day.

He diagnosticated the presence of these neoplasms by close and careful inspection, together with the subjective symptoms; he operated for their removal by laryngo-tracheotomy, and he healed cases of œdema of the glottis by scarifications and strong solutions of nitrate of silver.

In Dr. Green's article, published in 1857, on Lesions of the Epiglottis, there is a careful description of the minute anatomy of the cartilage, showing that its mucous membrane adheres closely to the cartilage on the laryngeal face, there being no areolar tissue interposed between the lining membrane and the cartilage, whereas beneath the mucous membrane on its anterior or lingual surface considerable areolar tissue is deposited. Disease, therefore, affecting this fibro-cartilage must have its seat either in the mucous membrane or its follicles or in the subjacent areolar tissue.

He reviews the physiology of the epiglottis, calling attention to its very slight sensibility in health. While in its normal condition it is almost insensible—for it may be touched by the finger or with the handle of an instrument without producing any irritation—yet when it is inflamed it becomes much more sensitive and causes pain. When the lips of the glottis are reached a convulsive cough is produced. Dr. Green dwells on the function of this cartilage, together with other parts, in the protection of the larynx, as also of the supraglottic space. He writes, first, of the erosions or abrasions of its mucous membrane; secondly, of ulcerations of the membrane and of the glands; thirdly, of œdema or infiltrations of its areolar tissue.

These lesions of the epiglottis he justly maintains are of much greater frequency than has been generally supposed. Persistent coughs have been kept up by the presence of undetected erosions of the epiglottis. These he had greatly benefited by applications of lunar caustic. Dr. Green contended that the direct medication of the lungs by means of catheterism of the air tubes, an operation not before performed by any one, he had repeatedly accomplished, that the operation might be performed by the dexterous surgeon with ease and facility and with perfect safety to the patient, and that the results of this method of treating disease, whether it had been employed in bronchial affections or in the commencement of tuberculosis, had been very encouraging. Dr. Green reported one hundred and six cases of tuberculosis and chronic bronchitis treated by him, especially by catheterism of the air-passages, with great success. Following Dr. Green, Professor Hughes Bennett reported that he had repeatedly acted upon Dr. Green's suggestion with success. In Green's report (1859) on the Difficulties and Advantages of Catheterism of the Air-passage, he quotes freely from Bennett, Trousseau, Loiseau, Blondeau, and others—all strongly in favor, from their personal experience, of injecting the air-passages. The death of Mr. Whitney fourteen days after Dr. Green had passed an instrument into his throat prejudiced many against him; he had pushed the instrument with some force through an obstruction. In operating, he felt something give way—an abscess probably. Mr. Whitney's death created a great sensation. Trousseau, Bennett, and Rokitansky wrote letters after receiving the details, stating that they did not think the operation had anything to do with it. Trousseau said the abscess existed before the operation.

Dr. Horace Green encountered great opposition throughout his professional life. His originality and his persistent maintenance of his views, which he knew were founded upon close observation, attracted much attention and caused no little jealousy. I may be allowed to say that, after having practiced in 1854 upon Dr. Green's views, and subsequently (1859) with M. Buchut's suggestion in catheterizing the larynx, I determined to go to New York to see Dr. Green and to get some practical points from him. I did so, but, after reaching New York, I was dissuaded by prominent New York physicians from calling on him. Some of them said he was a charlatan who was guilty of pretending to do what he could not do. I now regret that I left the city without seeing him.

This occurred when the feeling against Dr. Green had culminated and a committee of the New York Academy of Medicine had been appointed to investigate Dr. Green's views. So great was the feeling against Dr. Green in New York that the Academy of Medicine, after their committee had made their report, which was a divided one, although they could not convict him, yet they did him the injury of allowing no vote to be taken, and the report remained for over five years on their table unacted upon. Afterward, although men of the highest character indorsed him and his statements, they did not, as far as I can ascertain, withdraw the charges against him.

Why was Dr. Green so unpopular with his professional brethren? He certainly was a gentleman of high culture and great ability, very laborious, conscientious, and persevering. His great success made him a mark for jealousy. His studies and his taste led him to carve out for himself a specialty when specialties were not considered allowable. All specialism, particularly ours, was considered questionable from an ethical point of view.

Dr. Green was calculated to be a leader in medical thought. Had his health permitted, he would have availed himself in his declining years of Garcia's discovery, and no doubt would have enriched the new science of laryngoscopy by his accurate observations.

Time and justice have rescued his reputation. As Americans we are proud of him. We gratefully acknowledge that his works revolutionized the pathology and treatment of laryngeal disease. "His researches," says our eminent president, "formed an epoch in the study of laryngeal inflammation." They dissipated the clouds that surrounded laryngology and assisted at the dawn of laryngoscopy.

Our former secretary, in his wonderfully accurate photograph of our fellows, appropriately placed Dr. Horace Green as the central figure.

Action of Cod-liver Oil.—"MM. Gautier and Mourgues, in a recent communication to the Academy of Sciences, discuss at some length the reasons why cod-liver oil is superior to other fats as a therapeutical agent, and arrive at the following conclusions: 1. It is more easily assimilated, owing to its containing free fatty acids and some biliary matters which render its emulsion specially easy when it comes in contact with the pancreatic juice. 2. It is rich in phosphates, phosphoric acid, lecithin, and phosphorus in organic combination; the phosphorus, especially in the last-mentioned form, is very readily assimilated to form protoplasm, and thus nutrition is greatly stimulated. The small amounts of bromine and iodine being also present as organic compounds exercise a beneficial influence on the general metabolism. 3. The alkaloids present—butylamine, amylamine, morrhuine—and morrhuic acid stimulate the nervous system, increase the amount of sweat and urine, and act as nervine tonics."—*British Medical Journal.*

OCULAR DEFECTS AS A FREQUENT CAUSE OF HEADACHE.*

By WILLIAM HOLLAND WILMER, M. D.,
WASHINGTON, D. C.

If there is one malady more than all others that has taxed the ingenuity of the physician in regard to alleviation or cure, that one is headache. The brain, with its coverings, as a part of the body, and not an isolated organ, has a more or less close connection by nerves and blood current with other organs; and experience has established the fact that disorders existing in distant portions of the body, among other manifestations, may exhibit themselves in the form of headache. Therefore, a symptom ætiologically and pathologically so complex can not be relieved by any single remedy. It is only by tracing the symptom to its cause, and by removing or correcting it, that we can hope to afford relief. A very frequent cause of head pain is some defect in the visual apparatus, but the causal relation between the two has only of late obtained due recognition. Recently, not a little has been written upon this subject, but it is not the writer's object to give the literature, but simply his personal experience with this class of cases.

Here let me say parenthetically that I do not intend to exclude other causes of headache. Our *confrères* the general practitioners are prone to believe that the specialist has become so warped by specialism that he can behold only the *mote* in the eye, while the *beam* in other organs is not recognized. I must admit that there has been ground for this opinion. Some of us, like the birds and species of reptiles, seem to have developed a mental membrana nictitans by which we exclude from our sight all portions of our patients' bodies except their eyes. For the past few years the writer has carefully noted the clinical features of the cases as well as corrected the ocular defects.

The headaches which the ophthalmologist meets with fall under two classes: One, in which the symptom is directly traceable to the use of the eyes and is accompanied by other signs of asthenopia—such as weak feeling of the eyes, watering, strained sensation, and inability to use them for any length of time. In the other class, the vision is apparently perfect and the eyes themselves free from pain, yet headache is often severe. I do not recall a single case coming under the first classification in which the headache was not cured, or relieved, by the proper glasses.

Cases under the second category generally come to the oculist after previous medical treatment, and frequently by the advice of the family physician, or, as a *dernier ressort*, at the suggestion of a friend. Such patients attribute their headache to some other organ than the eye; for it is difficult for them to understand how headache can result from eye strain when the vision is good and the eyes themselves free from pain.

In cases of this division a goodly proportion of headaches were relieved or cured by the systematic use of glasses —often to the joy and surprise of the patient. However, nothing can bring out the point so well as a recital of a few of the most interesting cases, which I will give in some little detail even at the risk of becoming tedious.

I select at random a few cases in which the age of the patient, the refraction error, and the length of duration of the headache vary. I am indebted to my friend Dr. Gruening, of New York, for the use of his case books, from which these cases were taken:

Case I. *Hyperopia.*—E. M., aged nine, came to the office with the following history: Vision had been apparently perfect until three days before, when he noticed that figures on the blackboard, which were previously clearly seen, could no longer be recognized. He had suffered from frequent headache since he first started to school, but during the past three days has had constant dull pain in forehead and temples. Sight in either eye one fifth of normal. Tested by glasses, there was an apparent myopia of $\frac{1}{24}$. With this correction, the vision for distance was normal. One hour after the instillation of a one-per-cent. solution of atropine the pupils were fully dilated and patient said that his head felt better than it had for three days. At this time a hyperopia of $\frac{1}{48}$ was found. Three days later patient returned, after the systematic use of atropine, with the statement that he had had no return of the headache since last visit. He showed a total hyperopia of $\frac{1}{30}$ at this visit, and glasses correcting the full defect were given. There has been no return of the headache.

Case II. *Compound Myopic Astigmatism.*—V. M., aged fifty-two, was seen in November, 1888. He complained of great difficulty in reading, especially by artificial light. Upon being questioned, he said that he had more or less constant dull pain in the head, principally at the back part. He added that he did not expect to be relieved of that. He had never worn glasses. Sight in either eye $= \frac{2}{3}$; with the proper correction, normal. A combined concave cylindrical and spherical glass was prescribed for the distance, while for reading the astigmatism and presbyopia were corrected by another glass. The headache, with the other symptoms of asthenopia, disappeared after the use of the glasses.

Case III. *Mixed Astigmatism.*—J. F., aged thirty-five, is the last that I will recite. The patient, a Wall Street broker, came to the office in April of the past year. He suffered from insomnia and from headache which extended from the top to the back of the head. Prolonged medical treatment had given no relief other than the production of sleep by hypnotics. Sight $= \frac{2}{7}$; with the correction, $= \frac{2}{3} +$. The hyperopic element of the astigmatism, which was predominant, was corrected temporarily, and the patient informed that it would probably be necessary to re-examine the eyes under a mydriatic, when other glasses could be prescribed. The patient received his glasses the same afternoon, and returned three days later to report that during the past few days he had been free from headache, and had slept without a hypnotic better than he had done for years. The relief was so great that another examination has been thus far not imperative.

In the first case the *constant* headache was of only three days' duration and came on at the same time as the ocular symptom of near-sight. Owing to the spasm of the ciliary muscle, not only was the existing hyperopia masked, but apparent myopia produced. The headache was relieved when the ciliary muscle was put at rest by atropine.

The headache in the next case had lasted through the patient's lifetime, but had not been attributed to the eyes; in fact, it was only the other symptoms of asthenopia that brought him to an oculist.

* Abstract of a paper read before the Medical Society of the District of Columbia, May 28, 1890.

The third case is interesting on account of the reflex nervous symptoms that accompanied the headache. The glasses relieved him when three years of medical treatment and traveling had failed.

As the correction of an ocular error can relieve headache, so the production of such a defect artificially may cause it. This fact is exemplified in the writer's experience with *dark curved* glasses. All glasses of this description brought by patients to the office during the two years following September, 1887, were examined and their refraction noted. They, without exception, possessed the action of a concave glass in one or all meridians. There were concave sphericals, the same with concave cylinders, and, with these, a variety of combinations with prisms. In the majority of cases the glasses were irregularly concave. The cheaper grade of glasses worn by dispensary patients presented the same defects to a greater degree. The writer has had some personal experience with headaches from this cause. Some years ago I purchased colored glasses to wear while traveling. For a short while they were agreeable, but in the course of half an hour pain extending from forehead to occiput supervened. A slight amount of hyperopic astigmatism in my case will account for the pain caused by the irregularly concave glasses.

Not by any means can every headache be cured by glasses. It may require the care of the general physician, the gynæcologist, the rhinologist, the neurologist, or even the surgeon.

The headaches that belong to the domain of the general practitioner are legion, e. g., the various toxæmic headaches and those dependent upon other general disorders. Again, we all know of frontal headaches due to disease of the frontal sinuses or to nasal occlusion.

In conclusion, I think we may safely say that headaches, even where the eyes seem perfect, can frequently be cured by properly adjusted glasses.

At times, the true condition of the eyes can only be found under the influence of a mydriatic. Especially is this the case with children.

The fact that headache disappears under the influence of a mydriatic gives ground for prognosticating relief by glasses.

Flat smoked glasses should be worn, if a colored glass is necessary, when the patient is not myopic or when the accommodation is not completely paralyzed.

Finally, the existence or non-existence of eye strain should at least be known in cases of obstinate cephalalgia before any course of treatment can be intelligently adopted.

Antipyrine for Erysipelas.—"Dr. Favre, of Fribourg, relates an unusually severe case of erysipelas, showing the high curative value of antipyrine. A woman, aged thirty, suffered from facial erysipelas accompanied by somnolence, vomiting, constipation, and high fever. In spite of the local application of cold, carbolic acid, ichthyol, corrosive sublimate, strips of adhesive plaster, etc., the morbid process gradually spread over the scalp, neck, chest, upper extremities, abdomen, and buttocks. On the tenth day the administration of antipyrine was commenced, with the result that fever at once markedly decreased, the patient's objective state greatly improved, and the erysipelas soon ceased to spread."—*British and Colonial Druggist.*

HÆMORRHAGE AFTER AMYGDALOTOMY,

WITH A DESCRIPTION OF A GALVANO-CAUTERY AMYGDALOTOME.

By JONATHAN WRIGHT, M. D.,
BROOKLYN.

The question of hæmorrhage after amygdalotomy has been the theme of many animated discussions in various society meetings. The symptoms for which amygdalotomy is usually performed are, as a rule, so little threatening to life and to comparatively good health that it has seemed to many that even the few cases reported of serious hæmorrhage form a contra-indication to the operation. On the other hand, the less conservative are disposed to disregard the danger, estimating it as infinitely small, pointing both to the extremely small percentage of cases of dangerous hæmorrhage when all amygdalotomies are considered, and to the assertion * that no case of *fatal* hæmorrhage with modern methods has ever been reported. These are two extremes of opinion, much of it expressed in the heat of debate. This is one of the many questions where a mean position is probably the more tenable.

It has never been my misfortune to have any case of considerable hæmorrhage following amygdalotomy, neither has any such case come under my direct observation in the practice of others; but in looking over the literature of the subject, as well as in considering the cases which have come to my knowledge, the fact has been very apparent, and the remark has frequently been made before by others, that in the very large majority of cases the patients were adults. The fibroid elements in a hypertrophied tonsil, which always increase relatively as age advances, and often absolutely, form a less favorable tissue for the retraction and closure of cut vessels than the soft, spongy mass of a young tonsil made up largely of lymphoid tissue.

In order to ascertain how many of the cases of hæmorrhage reported after amygdalotomy were in adult patients, I have requested Dr. R. Lorini, of Washington, to search the records of the last twenty-five years in the Surgeon-General's office. Dr. Lorini has not been able to find the articles denoted by the following references: De Blois, *Boston Med. and Surg. Jour.*, Mar., 1887, p. 309; Billroth, *Aerztl. Intell.-Blatt*, 1870, No. 31, and *Wien. med. Woch.*, 1870, No. 49. The following-named journals were not accessible at the time of making the search, the volumes being at the Government bindery: *Med. Record*, xxiii, 1883; *N. Y. Med. Jour.*, I, 1889. Dr. Lorini remarks that Ricordeau, in his thesis, states that Cheselden reported two cases of death from hæmorrhage after removal of the tonsils with the bistoury, no details being given. I insert herewith the report as he made it to me.

Several facts are especially noteworthy.

It will be seen that the total number of cases reported is not so large as might be expected. It will also be seen that in the list are two fatal cases, one in an adult of twenty-four or twenty-five, in which no mention is made of the instrument used. The other fatal case was in a boy of eight

---

* Since this table was compiled I note the report of a case of hæmorrhage after amygdalotomy, in a child seven years old, during active inflammation of the tonsils. (Moure, reference in *Jour. of Laryng.*, 1890, No. 8.)

years and a half, in which the operation was performed with an amygdalotome. The cause of death in the latter instance was the wounding of the internal carotid artery, which pursued an anomalous course, so that no precaution could have averted the catastrophe.*

Delavan's case of hæmophilia is the only other one in which the age is given where the patient was a child.

It is, of course, impossible to say how many unreported instances of hæmorrhage have occurred. There is hardly a physician who has not heard of or observed one or more. When we consider how comparatively few amygdalotomies are done after the age of eighteen or twenty, the chances of the occurrence of a very undesirable amount of hæmorrhage in any given adult case are not so few as to be disregarded if there is any way of lessening the danger. The question of fatality or recovery from the immediate effects of the hæmorrhage is not the only one to be considered. The loss of a large quantity of blood may often cause serious impairment of the general health for many months. It is a common cause of chronic anæmia, an affection which most frequently baffles the skill of the physician and exhausts the patience of friends. Although the operator himself may not be unduly alarmed, unless, as in one case in the list, he himself happens to be the victim, the patient and his friends are always, in spite of the most positive assurances, greatly agitated.

When all these facts are considered, I can not see how amygdalotomy under ordinary indications is a justifiable operation in adults when there is a safer and quite as efficient method of procedure. On the other hand, I am unable to perceive why any other than the cutting operation should be done in children, since the danger is practically *nil* and the difficulties of other procedures are very much greater.

Ignipuncture has been extensively used as a substitute for amygdalotomy. I have employed it in a large number of cases, and a year or two ago gave a short account of my experience in a letter to the *Medical News*, March 24, 1888. In children it is only of value in my experience where the tonsillar tissue is diffuse and does not project beyond the faucial pillars. In these cases a cutting operation is ineffectual and usually impossible. If the child is tractable and cocaine is applied, the platinum point of the galvano-cautery can frequently be used advantageously to burn down the irregular nodules of lymphoid tissue between the pillars. In burning adult tonsils, eight to twelve sittings are often necessary, the number, of course, depending upon the size and extent of the hypertrophy. There must be a week or ten days between each sitting. Occasionally, in spite of cocaine, the applications are disagreeably painful, especially toward the last, when the hot wire is used in close proximity to the mucous membrane. In the above-given table a case of hæmorrhage after the cautery has been reported. It is a little hard to understand how such a thing could occur to any sensible operator or with any reasonable procedure unless a vessel of very large size (internal carotid) was wounded by the penetration of the hot point. Nevertheless, the case should be kept in mind.

Notwithstanding these disadvantages, I believe ignipuncture in adults preferable to amygdalotomy. Preferable to both, however, is the removal by the galvano-cautery snare as recommended by Dr. Knight.* I have used it several times, both before and since the appearance of the paper. The principal objection to it is the extreme difficulty frequently encountered in the satisfactory adjustment of the platinum or irido-platinum loop. The reflex movements of the patient's throat are often so pronounced as to render the procedure almost impossible. After my clothing had formed the repository of the contents of one patient's stomach, I began to cast about me for some pleasanter method of accomplishing my purpose. The instrument figured here has been the result.

As will be seen at a glance, it is the adaptation of an ordinary Mackenzie amygdalotome to galvano-cautery purposes. Instead of the steel blade with the convex cutting edge, a non-conducting material (compressed paper) is used, and one end hollowed out into a crescent. Across this is stretched a platinum wire which represents the sharp edge of the cutting instrument. This is connected by means of copper wires, inlaid along the sides of the blade, with the binding screws at the other end. Here, by means of the ordinary spring, the circuit from a cautery battery is closed by the pressure of the thumb as the blade is driven against the mass included in the loop of the instrument when adjusted. The frame of the instrument is the same as that of the Mackenzie. The platinum and copper wires are so arranged that the former can be cheaply and easily replaced when by accident it is burned through.

Of course this instrument can be as easily adjusted as the ordinary amygdalotome. The tonsil can be severed as quickly as with a knife if the wire is heated white hot, but by regulating the current the operation can be done as slowly as may be thought desirable. It must be remembered that more of the tonsil is destroyed than is represented by the part cut away, the cauterization of the stump causing marked retraction after healing. With the galvano-cautery snare the edges of the faucial pillars are apt to be severely cauterized, often causing great pain for several days after the operation. This is entirely avoided by the galvano-cautery amygdalotome. I can not say that the device will

* Dr. Lorini assures me that no mention of these cases can be found outside of Ricordeau's thesis.

* *Trans. of the Am. Laryngol. Assoc.*, 1889, p. 79.

entirely abolish all danger of secondary hæmorrhage, but it must be apparent to every one that it will greatly diminish the risk. I have not as yet had an opportunity of using the instrument extensively, but I present it because I can not, theoretically, see why it should not do the work required with a great diminution of the risk.

In one case of large, flat fibrous tonsils, it removed them on both sides with very little pain (the patient complained of none) and no hæmorrhage whatever. The retraction of the stumps has been more marked than usual where they are adherent to the pillars on all sides.

I am indebted to the surgical-instrument department of Hazard, Hazard, & Co. for the execution of the idea.

A PRACTITIONER'S EXPERIENCE IN INFANT-FEEDING.

By CUVIER R. MARSHALL, A.M., M.D.,
PHILADELPHIA.

It may seem to be almost a useless waste of time to attempt to add anything to the volumes of matter which have been written upon the subject of infant-feeding, and the only excuse the writer has to offer for the present intrusion upon the time and patience of the busy readers of the *New York Medical Journal* is a desire to present the results of a summer's experience in the management of artificially fed infants. I am of the number of those who believe that cow's milk is the best substitute for the mother's milk in the vast majority of cases. I have met with instances among the poor where children of from two to four months of age have been fed on cold cow's milk, undiluted, except when that precaution had been kindly taken by the milkman before delivery. In many of these cases apparently no evil results were noticeable. I have frequently seen upon the streets of our cities infants being wheeled about with the omnipresent nursing-bottle conveniently arranged in such a position as to enable the child to feed at pleasure without any regard to proper periods of digestion, and yet those children seemed to thrive. These facts are not offered in support of such improper methods, for they can not be too strongly condemned; and we all know how, on the other hand, a very slight departure from the strictest cleanliness or the greatest care in the preparation of the milk will bring on, in many infants, various types of gastric and intestinal derangement. I was once very favorably impressed with the possible value of some of the artificially prepared foods of the Liebig class, the so called malted foods, but, after having given them a fair trial, I was led to conclude that they would give satisfactory results in exceptional cases only. The class of infants with which we, as general practitioners, have to deal with reference to the regulation of the diet is that large number of puny, sickly children possessed of very feeble digestive powers, with which class I have found the malted foods to disagree, producing vomiting, and, on account of their laxative properties, diarrhœa. In my experience, the wheat foods should not be given to young infants unless everything in the milk line has been proved to be impracticable; young infants can not digest starch, and, although some very able writers and teachers advise the use of starch in these cases, I am unable to obtain the results alleged for this class of foods. One leading authority has asserted that the addition of a small quantity of barley water or oat-meal water to cow's milk will prevent the curdling of the casein in large masses; but I have failed to obtain any such much-desired result from that procedure. Starch is digested in the infant by the saliva; the young infant does not secrete a large quantity of that fluid, and, even if it did, it does not masticate the food and incorporate with it the saliva as the adult does; but the starchy food being received immediately into the stomach ferments there, and is apt to give rise to unpleasant results.

The most efficient agent for the artificial digestion of milk which has been brought out by modern enterprise is the extract of pancreas, as prepared by several well-known firms. By its use the casein may be completely converted into peptone for use in cases of children of very feeble constitution, or it may be only partially digested for stronger infants, in which condition, on the addition of a few drops of any acid, the casein will precipitate in fine flakes, the effect resembling that produced by the action of the gastric juice on human milk. Any one can make this experiment for himself, and it will show at once the great value of this agent in the preparation of infant food: Warm a small quantity of fresh milk, and pour an equal portion into each of two test tubes; note the reaction of both specimens, and, if not alkaline, add a few grains of bicarbonate of sodium; and into one test tube drop a grain of a good extract of pancreas; shake both tubes and allow them to stand for eight or ten minutes; at the expiration of that time, add to each sample a few drops of nitric acid and observe the result. The casein in the sample treated with pancreatin will precipitate in fine flakes, while that in the other tube will be curdled in dense, ropy masses, just as the same result is produced in the stomach of the infant by the acid gastric juice. The method of artificial feeding which I have adopted after much study and careful reading and observation is the following: Care is taken to obtain the milk from a reliable dealer. The milk supply of the city of Philadelphia is derived chiefly from the adjoining counties, and it is not difficult to obtain a very fair quality of milk. A number of ordinary prescription bottles are obtained, varying in size according to the age and weight of the child; these bottles are thoroughly cleansed and sterilized by boiling them for twenty minutes. While this is going on the milk is also sterilized by boiling, in the absence of the modern sterilizer, and at the end of the period of twenty minutes the bottles are immediately filled and tightly corked, the corks also having been boiled with the bottles. After cooling, the bottles are laid on ice until required for use. When the time for feeding has come, one bottle is opened and the contents are mixed with an equal quantity of boiling water; the temperature of this mixture will be about right for feeding, and in many cases it may be given without further treatment. When the stomach of the infant is in such an irritable condition that even sterilized milk will not agree with it, I am in the habit of using the

pancreatic extract of the Fairchilds to partially or completely predigest the milk for administration. The mixture of milk and boiling water having been prepared as above, a few drops of a saturated solution of sodium bicarbonate are added (sufficient to render the reaction alkaline), and this is followed by the addition of a small quantity of extractum pancreatis, from one to three grains being used, according to the quantity of milk to be treated. The mixture is well shaken and allowed to stand at a uniform temperature of about 100° for from six to twenty minutes, when it is ready for use, the amount of undigested casein, of course, decreasing as the process is prolonged. My rule is to feed about every two hours in very young infants, about once in three hours being often enough after the second month.

I am sure that I have succeeded in saving the lives of infants in hot weather by the above-described process when every other method or article tried proved useless. The extra trouble involved is more than is ordinarily required to prepare the food, but after a few trials the process becomes quite simple. The articles required are from six to ten bottles (varying in size from two ounces to six in capacity), a few corks, a bottle of a saturated solution of sodium bicarbonate, and a quantity of a good extract of pancreas. The peptogenic milk powder of the Fairchilds is a very excellent article, and it probably enables us to so modify cow's milk as to obtain as perfect an imitation of human milk as it is possible to produce in the laboratory. I have used it with success, and the only objection which I have to it is the fact that, on account of the alkaline salts which it contains, the kidneys are powerfully stimulated and the urine is rendered alkaline, offensive, and abundant. The use of any artificially digested food is not to be continued for a longer time than is necessary to bridge over a critical period in the life of the infant, and as soon as the cool weather of the fall months returns, an attempt should be made to substitute for it pure cow's milk, properly diluted with water, according to the age of the child.

HYPERTROPHY OF THE TURBINATED BODIES, AND THE EVILS RESULTING THEREFROM.*

By CHARLES R. WEED, M. D.,
UTICA, N. Y.

In presenting for your consideration my subject to-day, I shall endeavor to be as brief as possible, refraining from lengthy anatomical and physiological details and descriptions, assuming that with these branches you are all familiar. Medical literature teems with the various diseases originating from turbinated hypertrophies, and to their cause, prognosis, and treatment I shall confine myself.

To the specialist I think I am justified in saying that, of the major number of nasal troubles that come within his province and that he is called upon to treat, anterior and posterior hypertrophic rhinitis stand pre-eminently first. During my residence here I have found that many so-called simple catarrhs arise solely from these hypertrophic conditions, which, unfortunately, have not been recognized early enough to have effected the relief sought for.

To simplify my subject I will divide the nasal cavity into its two regions: First, the olfactory, which includes the superior and the upper half of the middle turbinated bones. The membrane in this situation is more closely adherent to the periosteum and relatively thinner than in the second or respiratory area, is less vascular, and but moderately supplied with serous glands. Its nerve supply comes from the terminal branches of the olfactory, which, with nerves of sensation, are distributed solely to this region after passing through the apertures of the cribriform plate of the ethmoid. The superficial lining of this area of special sense is freely provided with cells (the olfactory cells of Schultz), and if these are destroyed the sense of smell is lost as completely as though the lobes or nerves had been divided.

The second, or respiratory region, includes the inferior turbinated bodies as supplied by the nerves of the fifth pair. The glands in this location are both mucous and serous, and considerably larger than those of the olfactory region. Their alveoli are filled with globules of fatty matter; hence in ozæna the crusts and discharges always contain decomposing fatty globules, which give rise to its characteristic offensive odor. So much for the regional structures; and now for the changes in them.

First, the most frequent cause of hypertrophy is the destruction of the vibrissæ, or hairs in the nostrils, they acting as the sentinels that guard the entrance to the respiratory tract from floating dust and coarse particles. The moist and ciliated mucosa, by its irregular contour and vibratile cilia, is specially adapted to hold the finer particles. These, on being deposited, act by stimulating the glands. Then a secretion is poured out, and this cleans the nostrils. Now, in connection with the hairs, if these cilia are destroyed, the above function necessarily ceases, and an inflammation begins which, if not treated at once, will result in hypertrophy. I always warn my male patients (for the habit I am about to mention is fortunately confined to our sex) against pulling the hairs from the nostrils—a habit not only pernicious in the extreme, but disgusting as well. The membrane covering the bones is first affected, becoming thickened in its three layers by constant irritation, and presents to the rhinoscopist a turgid, swollen appearance. Anteriorly the surface of the inferior turbinated bones is most prominent, and at times the membrane is so thickened as to cause complete stenosis by pressure against the septum. The middle turbinated, where the hypertrophy is great, takes more of a horizontal position; the membrane is more or less red according to the intensity of the inflammation present. This condition, if allowed to increase, results finally in the bony structures becoming hypertrophied, the posterior ends showing the condition, which requires a careful rhinoscopic examination to determine.

Of the varieties of hypertrophy there are two, the white and purple, the former being far more commonly met with than the latter. In shape they are rounded, their surface irregular, and their location posterior, often compressing the

* Read before the Medical Society of the County of Oneida, July 8, 1890.

Eustachian orifices. This is particularly the case with the inferior turbinated bodies. The above conditions constitute the diseases known as hypertrophic rhinitis, anterior and posterior. Resulting from these conditions and the most frequent of all troubles is, first, deafness from pressure upon and occlusion of the Eustachian apertures; next, neoplasms of various kinds, polypi, ulcers, etc; pharyngeal disease, with its various conditions; laryngeal disease, resulting from the constant irritation produced by the dropping into the throat of the retained post-nasal secretions and the hawking process to dislodge them, often resulting in a catarrhal laryngitis and ultimately in consumption. Asthma is a very frequent sequela. Schmiegelow, of Copenhagen, in an essay published in London this year, places the cases of asthma caused by nasal diseases at about ten per cent. in males and six per cent. in females, and the cases tabulated, without exception, were cured by the result of proper treatment of the nasal passages. Hack, in his work published in 1884, although exaggerating the reflex conditions arising from hypertrophies, is nevertheless entitled to the credit of being really the first rhinologist to establish that asthma resulting from the hypertrophy of the turbinated bodies is a fact. Woolen says that asthma is especially due to hypertrophy of the posterior tips of the inferior turbinated bones and occasionally of the middle ones, which either touch the septum or curl on themselves and touch the outer wall of the nose. This same writer considers hypertrophy of the anterior tips the essential local factor of hay fever; while in our own country such men as Roe, of Rochester, Daly, of Pittsburgh, Sajous, of Philadelphia, and Bosworth, of New York, all agree with the foreign authorities just quoted. Hay fever, with its distressing symptoms, and even aphonia, caused, in my opinion, by a nervous reflex condition in persons of a highly sensitive nature, is another of the ills following these hypertrophic conditions. Cough in some cases is certainly from the same source. Vertigo is often present, and even epileptiform convulsions have been reported, though rarely, as arising from these hypertrophic conditions, while supra-orbital neuralgia, diffuse headache, and migraine almost invariably have their origin from nasal obstruction. I mention these diseases as being those most commonly complained of by patients suffering from hypertrophies. Of course, there are probably others more complex in character that we may be able to trace to the same origin, but, being rare, are naturally overlooked, and my time forbids a more extended research into them. I might add that Guye, of Amsterdam, Holland, finds aprosexia (inability to fix the attention) occurring mostly in young persons and especially would-be students—a condition due to nasal obstruction and hypertrophy; while Hill, of London, also tabulates a number of cases from this cause.

As to the treatment of these hypertrophies, it varies with different practitioners, as the cases present themselves, and according to the amount of thickening present. Of course, to relieve the hypertrophy is their first object, and for this purpose, if the membrane alone is diseased, the application of the galvano-cautery and the acids—nitric, chromic, and glacial acetic—may be tried. For myself I prefer the galvano-cautery as being more thorough and giving a quicker result. The almost universal treatment of spraying the nasal cavities with a two- or four-per-cent. solution of cocaine daily is to be condemned for two reasons: First, the relief is only temporary and simply tends to lessen any congestion of the membrane that may be present, while ultimately increasing the turgescence by causing an increased vascularity, and by, in many persons, setting up the cocaine habit. Lennox Browne, of London, freely condemns its indiscriminate use, showing that where there is a temporary relief from capillary engorgement of the turbinated bone, it results, if unduly prolonged, in anæmia with atrophy, or in an increase in the chronicity of the hyperæmia.

As regards the habit, I have had patients who, before consulting me, commencing with a two-per-cent. solution, have gradually increased it until a ten- or even a twelve-per-cent. solution has been used, showing how easily acquired this habit is.

Of course, where operations are necessary, either by the cautery, acids, or the cold snare, which may be used, then a six-per-cent. solution of cocaine thoroughly applied to the seat of the operation and solely for its anæsthetic effect is proper.

The next important step in the treatment is to see that the parts are kept clean by spraying with any of the mild and efficient alkaline solutions. Seiler's tablets are a very elegant preparation for this purpose, and for cleansing a coarse spray should be used, this to be followed by a nebulous spray of warm vaseline, which acts as a protective to the parts and hastens the cure.

Of course, while treating these cases it is necessary that your patients observe strict hygienic laws. I find it is a very good plan, where patients are able, to have them visit localities by the sea, for we are all aware how beneficial salt air is for those suffering from nasal troubles. The diet should be generous, bathing frequent, a fair amount of open-air exercise, and respiration through the nose.

Of course, should your patients be of a strumous diathesis, alteratives, with the different preparations of cod-liver oil, malt, etc., should be used.

A word in regard to the specula to be used in making examinations of the nose. The lighter and more delicate the better. The "Goodwillie" and "Folsom" are both to be commended, being light and very delicately made.

Meyrowitch has introduced a set of three that are admirable, being very light and self-sustaining.

Finally, I wish to add a few words of warning regarding the too frequent and indiscriminate cutting and gouging of the turbinated bones. Nasal plows, up-and-down saws, bone-gnawing forceps in the hands of the unskillful, inexperienced, and ambitious practitioner frequently cause great trouble, leading to more serious results than originally existed; whereas careful and delicate manipulation with the cautery or acids, though taking longer time, will, I am positive, repay you by the marked improvement following their use, and this, too, without submitting your patient to the torture of the cutting operations or to the dangers following them.

226 Genesee Street.

AN EARLY EXTRACTION OF CATARACT.

By S. DICKSON BARR, M. D.,
YORK, PA.,
MEMBER OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

Mrs. S. S., a farmer's wife, sixty-five years of age, came to me complaining of indistinct vision. Objects appeared as in a mist, while in picking up anything like pieces of money she would miss some of them. This dimness began last winter and was gradually growing worse.

She had always been myopic, a minus-five-dioptre glass being necessary to give a good sight of the optic nerve—that is, as good as could be had through the lens, which was growing opaque.

I found beginning cataracts in both eyes, that of the right one being further advanced than the left.

With the right eye she could count fingers at three feet, while with the left eye she was able to recognize people at about ten feet.

In the lens of the right eye I found a central opacity not implicating the entire thickness of the lens, while at the periphery was a semi-opaque rim.

The striæ showed clearly, the red reflection of the retina showing between, giving the whole lens the appearance of a wheel.

The left eye was in a like condition, but not so far advanced.

Usually we advise patients who have as much vision as this to wait for some time until there is no more vision than is necessary to distinguish light in a dark room. In this case the patient was anxious to have the operation performed, and I, believing that the lens was in a condition to be extracted (although not nearly in the stage of opacity generally thought necessary before an attempt to remove is made), agreed to operate.

My belief was based on the following ideas, and the results seem to verify them.

Donders represents that the refractive power of the eye is at its maximum in a child aged ten years, and that from that age it decreases until at the age of sixty it is lost entirely. Certainly the ciliary muscle does not begin to degenerate at this early age, for this would be incompatible with the state of the general muscular system. If it is not the ciliary muscle, then it must be the crystalline lens which changes, since the accommodation is due entirely to these two. So, at the age of sixty years we have the lens in a condition of solidity that can not be changed by any amount of action of the ciliary muscle.

Is not this lens in a condition solid enough to admit of removal if it were necessary? Why should we wait until the lens becomes entirely opaque and retrograde metamorphosis takes place before operating? I believe that the lens is in a better condition for extraction when the patient begins to complain of the appearance of a web over the eye, and the lens shows the characteristic milky appearance sufficient to satisfy the examiner that it is a cataract that he is dealing with, than it will be in if allowed to remain until the patient is totally blind. In the first case, the lens being solid at the age of sixty years from natural causes, has not become atrophied as yet, nor brittle or scaly, but is a solid mass of almost the consistence of gum; the corticle having still adhesive power enough to hold well together, and the milky appearance being indicative of the separation of the lens substance from the capsule, the cataract can, by slight pressure, be forced out without any of the particles scaling off. But when the lens is allowed to remain until it is entirely opaque, so that there is no red reflection, it becomes brittle and changes into "molecular detritus."

Then, when an attempt is made to remove this lens, in breaking the capsule with the cystotome, these brittle particles or scales are disturbed at the same time and fall away from the lens, and so create a great deal of after-trouble. Another objection to making the patient wait until the eye is entirely blind is the great inconvenience which the patient will have to put up with. One may have to wait for a year or more (generally more) before the eye attains the so-called ripeness. These are my ideas based on the result of observation in a number of cases of different stages of growth.

In the case noted at the beginning of this article I operated on the right eye, making a von Graefe linear incision in the superior portion at the corneo-scleral margin, about three millimetres below a tangent drawn to the superior margin, making a corneal flap. An average-size iridectomy was done and the capsule opened by inserting the cystotome first on the left side of the pupil and moving it up and down, then across in the inferior portion several times, then up and down at the right side and several times across the superior portion of the capsule, in this way cutting a square piece out of it. While doing this I was careful to catch the capsule with just the tip of the hook, and, to do this right, I had an assistant with a strong convex glass focus the light from a lamp held near the patient's head on the capsule and lens. Now, by very slight pressure on the inferior portion of the cornea, the lens came out without the slightest trouble, not a particle remaining.

The eye was cleansed thoroughly after making sure that the iris was clear of the edges of the wound, and, instilling a few drops of atropine solution, I bandaged the eye carefully and allowed it to remain so until the next day. When I examined the eye the next day I found the pupil clear with the exception of an almost imperceptible web in the inferior portion of the pupil. This disappeared by the next day, leaving a beautiful black pupil.

The patient did not have the slightest pain, although no opiates were given. Her vision is excellent. I shall operate in a week or so on the left eye, which will allow enough time for all inflammation to subside in the right eye. In this case, although the patient was highly myopic, not a drop of vitreous was lost; whether this was due to the early operation or not I am unable to say.

In performing any cataract operation I always provide myself with a small syringe to flush the anterior chamber and wash out any particles which might remain there, but I found it entirely unnecessary in this case.

One of the best syringes for this use is one made by Dr. Lippincott, of Pittsburgh, in which one can regulate the force of the flow.

I should like very much to get the opinions of other men on this subject.

HOMONYMOUS HEMIOPIC HALLUCINATIONS.

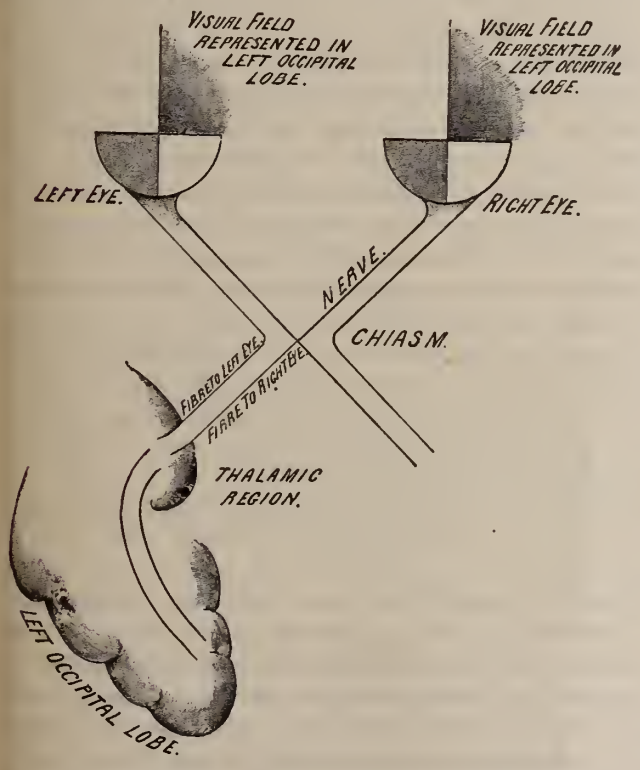
By FREDERICK PETERSON, M. D.,
CHIEF OF CLINIC, NERVOUS DEPARTMENT, VANDERBILT CLINIC.

The following history of a case of paranoia presents something unique in the way of visual hallucinations:

H. K., aged twenty, single, came to the Vanderbilt Clinic, June 10, 1890, complaining of persecution by unknown persons. He had noticed since January last that "mesmeric influences" were being used upon him, and the conspirators, three in number, have been redoubling their annoyances as time went on. He has unilateral hallucinations of hearing. There are three voices in his right ear, all talking to him and not to each other. They tease him, swear at him, curse him, and call him names. In addition to these uni-aural polyphonic hallucinations, he is tortured by disagreeable odors and by peculiar tastes in his water and food.

His visual hallucinations are singularly limited to the right visual areas of each eye, so that we may in fact speak of them as homonymous hemiopic hallucinations. He sees at times skeletons and various people, but always moving about and upon his right side, and this is true if either eye is shut. They never appear upon his left side. If he directs his eyes toward his right side, where the visions appear, they move still farther toward the right.

He complains of paræsthesiæ, flashes of heat and waves of cold through his body, jerkings of his muscles and viscera, and pains in his trunk and limbs, all of which he ascribes to electrical devices. Most of the pains in his trunk are restricted to the right side, but there is no unilateral distinction with regard to those of the limbs.



His hallucinations are conjoined with the delusions of persecution already mentioned. He thinks there are several persons, certainly three, who control him by mesmerism and annoy him by telephony and electricity. He has purchased a dozen books on mesmerism and clairvoyance, hoping to gain sufficient knowledge of the subject to be able to counteract the schemes of his enemies. Latterly his attention has been called to hypnotism and suggestion, and to the ease with which people may be influenced to commit theft and murder under such control, by reading the newspaper interviews with some of our leading specialists. He had copies of these interviews in his pocket and showed some of the illustrations, among which was that of a man, under hypnotic influence, plunging a dagger into another. The patient intimated that he had some fear of being made to carry out some nefarious undertaking by his imaginary hypnotizers.

Although no heredity could be ascertained, he exhibits marked facial asymmetry, and in particular a remarkable malformation of the hard palate, showing that he belongs to the superior degenerate classes. His is in fact a typical case of paranoia with systematized delusions of persecution which have been evolved from a degenerative soil.

The case is related, however, merely on account of the very remarkable character of the visual hallucinations. Their limitation to the right visual fields of both eyes is absolute proof of their central origin, and they doubtless arise through irritation in the cortical visual area of the left occipital lobe. It would seem as if the cortex of the left hemisphere were the chief seat of disturbance in this case.

Unilateral hallucinations of one eye alone, or uni-ocular hallucinations, have been described by several authors as occurring in the insane, but, so far as I know, this is the first reference that has been made to visual hallucinations of the character herein mentioned, and for which I can find no simpler name than that which forms the title of this article.

THE SURGICAL TREATMENT OF POST-TURBINATED HYPERTROPHY.*

By A. E. PRINCE, M. D.,
JACKSONVILLE, ILL.

The little that I have to say on the removal of the hypertrophied tissue which is found at the posterior extremity of the inferior turbinated bone is particularly addressed to those who have found difficulty in the successful removal of these enlargements with the time-honored snare and the various methods of cauterization. That they may be removed with the snare or destroyed by the galvano- or chemical cautery is not brought into question, but that the difficulties attending either of these methods in the majority of cases is not small I am convinced both by personal experience and by valid testimony of men who are not unskilled in the inspection and manipulation of these parts.

Nothing sounds easier than the operation as described by Bosworth in his recent volume on the *Nose and Throat*, page 151. "The loop, having been bent slightly to one side before entering the nares, will by its own elasticity slip over the mass, when it can easily be drawn into place and the tumefaction cut through." "Of course there is liability to be considerable hæmorrhage as the result of this procedure, but if the operation be done slowly, a half-hour or even an

* Read before the Illinois State Medical Society, May 6, 1890.

hour being consumed, it may often be done without loss of blood. If, however, hæmorrhage does occur, a plug of cotton can easily be passed back and wedged between the cut surface and the septum and allowed to remain until the next day if necessary."

The operation as above described is the standard operation for the removal of the posterior turbinated hypertrophy, and though it is usually efficient in the hands of a patient surgeon and has served the purpose in the past, there are, nevertheless, certain disadvantages, more or less real, which it may seem worth while to attempt to overcome.

The introduction of the wire and its adjustment over the tumor, so as to get the entire tumor into the loop, is not always easy. While tightening the loop over the growth, more or less of it may escape, often resulting in the removal of small portions and necessitating a repetition of the operation which is thereby made more difficult. In many of these cases the tumor consists more of dilated blood-vessels than actual hypertrophy, and in these cases it is almost impossible to apply the snare on account of its escape with the closure of the loop, in which case the removal of but a small portion of the mucous membrane may be the result. This difficulty is increased by the use of cocaine. The tedious nature of the operation, when attempt is made to avoid hæmorrhage, exhausts the patience of both patient and physician; besides, with the greatest prudence, hæmorrhage will rarely be avoided, and, when it occurs, the difficulty of ascertaining the result by ocular inspection is increased to such an extent that little is gained by an attempt at its prevention. Bosworth's procedure as recommended to arrest arterial hæmorrhage by "passing a plug of cotton back, and wedging it between the cut surface and the septum," will seldom succeed, because this space is wider than the anterior passage, and, besides, the hæmorrhage may not come from the lateral face but from the posterior end of the bone. Except in the purpuric state, I regard hæmorrhage as of no moment, because in the rare cases in which it does not spontaneously cease it may effectually be controlled at any loca-

tion by the use of a posterior plug, which can be introduced at a moment's warning with the aid of a soft catheter. With confidence in one's ability to execute this manœuvre all danger vanishes.

The substitute which is here offered for the snare is the curved turbinated forceps, which has served me in this class of cases for about two years. In its construction the excellent septum gouge of Weir has been taken as a model, and it has been made with sufficient length to reach into the pharynx. To it has been given the curve of the convex surface of the inferior turbinated bone. The handles are so curved and the pivot is so placed that it can be easily opened after it is introduced into position. The size is such that it can be readily passed through the inferior meatus. The blades are so made that while the biting edges come into exact contact, the edges on the convexity of the blades are cut away so as to prevent the material in the grasp of the blades from interfering with their perfect closure.

Experience commends the following method of procedure: The patient is placed in a recumbent position and O'Dwyer's gag is applied on the right side of the mouth. A canvas cone is placed over the mouth and the patient instructed to breathe deeply and rapidly with emphasis on the exhalation. Two drachms of ethyl bromide are now poured on the cone and the respiration is continued in the same artificial, rapid, deep manner. If we are successful in controlling the manner of breathing, the patient will be anæsthetized in thirty to forty seconds, when the forced respiration will be changed to natural slow breathing.

If from any cause this manner of breathing is not maintained, the ethyl anæsthesia is not certain to be profound, when chloroform or ether may be added. The next step is the introduction of the left index finger back of the palate, bringing it in contact with the posterior end of the inferior turbinated bone, where the tissue in question will be distinctly felt as a soft, yielding mass. The forceps is then introduced with the concavity downward and will be found to glide easily along the floor of the inferior meatus until it can be felt by the finger. The cutting edge is then rotated outward and the blades are separated. This movement will bring the tumor between the tips of the blades, the position of each of which can be precisely determined by the sense of touch. The blades are now closed on the tumor and the concavity is rotated downward and inward through a semicircle while being withdrawn, the effect of which is partly to cut and partly to tear the mucous tissues and vessels, thus favoring the early arrest of the inevitable hæmorrhage. The operation is repeated on the opposite side without removing the finger from the mouth. The patient is then placed in a position favorable to the escape of the blood, a portion of which is always swallowed. The hæmorrhage, though seemingly profuse at the time, does not continue more than a few minutes, and but little blood is actually lost. In but one case out of about fifty have I found it necessary to introduce a plug to control the hæmorrhage.

My excuse for detailing this procedure so minutely is found in the desire that some may be led to practice the bimanual manipulation, which will be found invaluable in the removal of the pharyngeal tonsil and other forms of nasal polypi as well as this. The form of the blades of the instrument, aided by the sense of touch, often enables one to reach the origin of a pedunculated polypus, and in some cases a small portion of bone has been removed with the pedicle, thus demonstrating the efficiency of the operation.

Trusting that the procedure may find favor at the hands of those who may see fit to give it a trial, I submit it for your criticism and consideration.

Anomalous Outlet of the Coronary Artery.—Meigs reports an autopsy (*Univ. Med. Mag.*, May, 1890) in which the opening of the right coronary artery was found to lie directly in the angle between the right coronary and intercoronary flaps.

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. APPLETON & Co.

Edited by FRANK P. FOSTER, M D.

NEW YORK, SATURDAY, AUGUST 30, 1890.

HYPNOTISM BEFORE THE BRITISH MEDICAL ASSOCIATION.

THE obscure phenomena of hypnotism were made the subject of serious attention at the recent meeting of the British Medical Association at Birmingham, when a paper on the subject was read by Dr. Norman Kerr, which was followed by a discussion that occupied the time of the Psychological Section for two days. The reader of the paper accepted practically all the alleged hypnotic phenomena as facts, but in hypnosis, after close watching, he saw only a distorted cerebral state, a condition with exaltation of receptivity and energy which was abnormal. Several questions had to be answered when we came to consider the applicability of hypnosis to therapeutics. Only a limited number of persons were susceptible, and even in these the after-effect was a disturbed mental balance and nerve exhaustion. Deterioration of brain and nerve function, with intellectual decadence and moral perversion, was apt to follow frequent repetition. Dr. Kerr, moreover, maintained that hypnosis itself was a departure from health, a diseased state, a true neurosis, embracing the lethargic, cataleptic, and somnambulistic states, and that, if a disease was cured by hypnotism, it would merely be by the substitution of another disease. Hypnotic suggestion might sometimes temporarily assuage suffering, but the underlying disease was not necessarily cured, though evanescent oblivion might be secured, and the lethal power of the morbid disorder was in most cases increased. The few patients he had seen apparently benefited had in no way been beyond the reach of ordinary treatment, but they resisted or were passive to that, while they gave themselves up to the mesmerizer, and became the subjects of what he called a jelly-fish slavery, which was worse than days and nights of pain and rendered their lives total wrecks. In the somnambulistic state subjects had been compelled by the operator's behest to commit crime. So serious were the evils that French surgeons had been prohibited from practicing hypnotism in the army and navy.

The gauntlet was taken up by Dr. Kingsbury, of Blackpool, who has adopted hypnotism in his practice and professes to have effected many cures by its agency. After describing the peculiarities of the two schools of Paris and Nancy, he entered into a discussion of the dangers of hypnotism and the range of its applicability, and detailed the clinical histories of cases treated by him by hypnotic suggestion. In one instance a patient suffered from sleeplessness, the result of a neuralgia. He hypnotized the subject, and left a paper with him on which was written: "Go to sleep at once and wake up to-morrow morning at 7.30. You will have no pain when you awake." And the experiment answered admirably. Seven out of ten persons were susceptible to the influence. He maintained that hypnotism was a useful adjunct to regular treatment, and said that it behooved medical men to become familiar with it, so as to be able to use it in special cases. Demonstrations were then given by Dr. Kingsbury and Dr. Tuckey on two subjects brought for the purpose from Manchester. The usual performances were gone through with, in no way differing from those commonly seen on the public platform.

A general discussion of the subject then took place, in the course of which Dr. Gairdner, of Glasgow, said he should leave the meeting in a somewhat different state of mind from that in which he entered it, and had not the smallest doubt that many other persons present would be in a similar state to his own. A great many years ago he had been disgusted by an exhibition of hypnotism in the drawing-room. While he did not doubt that there was a great psychic force involved in it, still, he had the strongest feeling that there was something, to use a Scotch expression, "no canny" about it, and that it was not for physicians to tamper with. Dr. Clifford Allbutt sided with the hypnotizers in the discussion, and referred to Dr. Norman Kerr's brilliant rhetoric, but failed to find in his discourse mention of any facts. If the profession did not take up the subject, it was sure to fall into the hands of quacks. He did not think that medical men were justified in throwing the whole thing overboard. Dr. Hack Tuke had been much interested in the phenomena, and thought the subject had a direct medico-legal bearing. He gave instances of patients who had been directly benefited by it. Another speaker, alluding to the moral aspect of the question, asked very pertinently whether any of those present would allow their wives or their daughters to be hypnotized except on the strongest possible grounds. If not, they had no right to hypnotize others. The opinion was very generally expressed that it was time for the government to put a stop to the disgusting public exhibitions of hypnotism which were becoming very prevalent, and that it would be well for the British Medical Association to appoint a committee to investigate the whole question of hypnotism and to give facilities for experiments upon lower animals as well as upon human beings.

On the whole, this discussion, which is the first occasion on which the subject has of late years gained the serious attention of the profession, will yield good results. The matter has been carefully considered. Evidence *pro* and *con* has been weighed, and both sides have had a fair hearing. To whatever length the friends of hypnotism may go in France, it is certain that in England its title to be considered a therapeutic agent of utility must be fully proved before it is accepted.

REMOVAL OF THE PUERPERAL SEPTIC UTERUS.

IN the *Deutsche Medizinal-Zeitung* we find the history of a case in which this procedure was resorted to by Dr. Stahl:

The patient was a primipara, thirty-five years of age, suffering with a subserous fibroma of the uterus. Her labor was

spontaneous, but the membranes were completely torn away at the border of the placenta, and remained *in utero*. Puerperal septic endometritis resulted, for which curetting, with disinfection of the uterine cavity, was done. Notwithstanding, puerperal sepsis resulted, with thrombosis of the pelvic veins and threatening general symptoms. Softening of the nodes of the fibroma was apparent, and the author performed supravaginal amputation of the uterus and employed extraperitoneal treatment of the stump. The conclusion from this case is that the membranes should be removed, if possible, immediately after the removal of the placenta, or they may bring about serious disaster to the patient.

Let us hope the conclusion may not be drawn that, if the membranes are not removed and sepsis takes place, amputation of the uterus will be the proper thing to do. It would be obviously unfair to say it should not have been done in this case, for the gentleman in charge of the case was probably a better judge as to its gravity than one could possibly be from the reading of a brief history. The moral that must always be drawn from the record of such cases is that it may furnish an excuse for many a similar operation when other means would be more suitable. Certainly, in puerperal endometritis, as cases go, even when complicated with subserous myomata, he would be a dangerous man who would counsel extirpation of the uterus as a means of treatment. In the balance, which would weigh the heavier—we mean in the average, yes, the majority of cases—a puerperal septic endometritis, or the dangers of the supravaginal extirpation added to the enfeebled condition resulting from sepsis? We leave out of consideration the question of removal of an important organ in a state of full functional power. The recent words of Greig Smith are golden words, that to sweep away the reproductive organs is retrograde surgery, unless it is necessary to save life.

MINOR PARAGRAPHS.

THE PROTEIDS IN THE URINE IN VARIOUS FORMS OF ALBUMINURIA.

Dr. D. Noel Patton, Mr. John Douglas, and Mr. Ronald Mackenzie publish in the *British Medical Journal* the results of numerous observations on albuminuria in acute and chronic parenchymatous nephritis, in amyloid disease of the kidney, and in heart disease, on functional albuminuria, and on the causes that increase or diminish albuminuria. They consider that Senator was right in the conclusion that, in all cases of albuminuria, both serum albumin and serum-globulin are present, though their proportions vary within wide limits, the quotient of the amount of serum-albumin divided by the amount of serum globulin being sometimes as low as 0·6 and sometimes as high even as 39. The quotient is high in acute nephritis when blood is absent, though globulin is in excess when hæmoglobin is present; the quotient sinks as low as 0·6 when the disease becomes chronic, the alteration depending on the condition of the patient. Amyloid disease can not be distinguished from the ordinary forms of chronic nephritis by the high proportion of serum-globulin, as maintained by Senator; and functional albuminuria is not characterized by the high proportion of serum-globulin, as suggested by Maguire. The proportion of the proteids to one another varies much in the course of the day, serum-globulin being always highest during the night and reaching its lowest point after breakfast, the amount of proteids passed bearing a tolerably direct proportion to the amount of the proteids taken, though a milk diet increases the proportion of serum-albumin. Apparently, high arterial pressure favors the transudation of serum albumin, while a low pressure increases the proportion of globulin transuded.

NEW TESTS FOR ALBUMIN.

The *Pharmaceutical Era* states that a new reagent to detect albumin, even in infinitesimal quantities, is said to exist in salicylsulphonic acid. This reagent is a body formed by the action of sulphuric acid on salicylic acid. It will affect as little as $\frac{1}{120}$ of a grain of albumin, making the urine turbid, but not affecting the other constituents, such as sugar, peptone, etc. In the *Johns Hopkins Hospital Bulletin* there is a report, by Dr. D. Meredith Reese, on trichloracetic acid as a test for albumin in urine. An editorial note in the *British Medical Journal* had called attention to this new test, which Boymond professes to have first brought into notice. This reagent precipitates albumin in cold solution, and is considered to rank among the most delicate tests. Under Dr. Reese's observation eighty-seven specimens of urine were examined. In twenty-five cases there was no reaction of any kind. In fourteen cases where there was no reaction in check-experiments the trichloracetic acid gave a precipitate. In eleven of these, granular, epithelial, and hyaline casts were found, and in three of these eleven cases the post-mortem showed distinct changes in the kidneys. In three cases where heat, acetic acid, and nitric acid gave no precipitate of albumin, a precipitate was obtained with picric and trichloracetic acids; and casts were found in these three instances. Trichloracetic acid is a delicate test, is prompt and easily applied, and gives no discoloration or colored zone.

CHRONIC INDURATION OF SUPERFICIAL VEINS.

According to the *Mercredi médical*, M. Duponchel has recently presented to the *Société médicale des hôpitaux* a patient suffering from a rare condition of the superficial veins. They were indurated and felt to the finger like atheromatous arteries. The condition was a chronic one, with subacute exacerbations now and then. The cephalic veins of both upper extremities and the left internal saphenous gave the sensation of a hard, resisting cord. A few days before, these same veins had felt like pipe-stems. Though rare, the trouble is of practical interest. It exists without varices or hæmorrhoids. Only once has the observer found cyanosis of the extremities. The hypothesis of chronic periphlebitis explains the venous induration; at the same time a morbid process similar to atheroma also suggests itself. When soldiers complain of vague pains without objective signs or painful points at intervals, such as characterize neuralgia, it is natural to suppose that the cases are simulated. Duponchel has frequently found an explanation of the alleged pain by a careful examination of the veins.

HYPNAL IN THE TREATMENT OF NEURALGIC INSOMNIA.

Dr. Fraenkel reports, in *Nouveaux remèdes*, that he has prescribed hypnal in various cases at his clinic, and that sleep resulted as with chloral and with the characteristics of the sleep produced by the latter drug—that is, a calm and refreshing sleep, without nausea or disagreeable sensations on awakening—and that the painful symptoms improved as they improve after the administration of antipyrine. Hypnal, or mono-

chloralantipyrine, is a chemically well-defined compound that is less soluble than either chloral or antipyrine; in the presence of a feeble alkali it is resolved into these substances, and this decomposition occurs in the blood or in the intestine. It has only a slight taste and odor, and is easily administered to children. It produces the hypnotic effect of chloral augmented by the analgesic action of antipyrine, and is especially valuable in insomnia caused by pain. It may be administered in capsules or powders, in doses of fifteen grains, to an adult, that may be repeated if necessary. For a child the dose is from a grain to ten grains.

FATAL POISONING WITH SALOL.

Dr. Hesselbach reports, in the *Fortschritte der Medicin*, the case of a young man suffering with rheumatism, who took by mistake two drachms of salol. Coma resulted, with great dryness of the tongue, anuria, and death on the second day. At the necropsy the kidneys were found to be soft, anæmic, and of a pale-yellow color; microscopically, the glomeruli were full of embryonic cells and leucocytes, the convoluted tubes were tumefied, and fatty degeneration had begun. The tubuli were filled with degenerated epithelium. There were no other lesions attributable to the drug. The toxic principle was the carbolic acid that is generated from salol in the system; and the author believes that it should be prescribed carefully, and the condition of the kidneys, as indicated by the urine, carefully watched.

THE CREMATION CONGRESS.

An International Congress on Cremation was opened at Berlin on August 4th. There were many foreign delegates present, and a resolution was passed expressing the hope that the governments that had hitherto opposed cremation would recognize the pernicious effects of inhumation and make cremation optional. Considering that the Roman Catholic Church has taken a position adverse to cremation, the acceptance of this proposition in Catholic countries is very doubtful.

ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending August 26, 1890:

DISEASES.	Week ending Aug. 19.		Week ending Aug. 26.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	40	12	37	11
Scarlet fever	18	3	14	3
Cerebro-spinal meningitis	2	0	0	0
Measles	104	13	79	12
Diphtheria	34	16	51	16

Government Measures against Hypnotism.—As an outcome of the expression of opinion at the Birmingham meeting of the British Medical Association a bill will be introduced at the next session of Parliament to restrict the public performances of hypnotic experiments which are now so much the fashion. There is no reason to doubt medical testimony to the effect that much injury is done to the health of the subjects of these public experiments.

Dr. Jonathan Adams Allen, of Chicago, died August 15th, at the age of sixty-five. He was identified with Rush Medical College for more than thirty years, having held the chair of theory and practice since 1859, and was president or dean for many years. He was one of the editors of the *Chicago Medical Journal* for several years. He wrote a book on life-insurance examinations which sold to the extent of thirty thousand copies. His contributions to medical literature were numerous, and his favorite subjects were nervous pathology, medical jurisprudence, mental capacity and alienation. He was for over twenty years the chief surgeon of a large system of railways in Illinois. As a teacher, he was eloquent, persuasive, and instructive, well prepared both by extensive reading and original research.

The American Association of Obstetricians and Gynæcologists will hold its next annual meeting in the hall of the College of Physicians, Philadelphia, on Tuesday, Wednesday, and Thursday, September 16th, 17th, and 18th. An invitation to attend the sessions is extended to all physicians who are interested.

The American Rhinological Association will hold its eighth annual meeting in Louisville, on the 6th, 7th, and 8th of October, under the presidency of Dr. A. G. Hobbs, of Atlanta.

Change of Address.—Dr. Gustav A. Pohl, to No. 96 Lemon Street, Buffalo, N. Y.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 3 to August 23, 1890:*

By direction of the Secretary of War, the ordinary leave of absence granted Kimball, James P., Major and Surgeon, in S. O. 152, July 1, 1890, from this office, is changed to leave of absence on surgeon's certificate of disability, with permission to leave the Division of the Missouri. Par. 7, S. O. 182, A. G. O., August 6, 1890.

Caldwell, Daniel G., Major and Surgeon, is, by direction of the Acting Secretary of War, granted leave of absence for one month and fifteen days, to take effect about August 15, 1890. Par. 1, S. O. 176, A. G. O., July 30, 1890, Washington, D. C.

Stephenson, William, Captain and Assistant Surgeon, now on duty at Columbus Barracks, Ohio, is, by direction of the Acting Secretary of War, assigned to temporary duty at Jefferson Barracks, Missouri, during the absence on leave of Major Daniel G. Caldwell, Surgeon, and will report accordingly. On the return to duty of Major Caldwell, Captain Stephenson will rejoin his proper station. Par. 2, S. O. 176, A. G. O., July 30, 1890, Washington, D. C.

Retirement.

Moore, John, Brigadier-General and Surgeon-General, August 16, 1890 (Act June 30, 1882). Headquarters of the Army, A. G. O., Washington, August 18, 1890.

Promotions.

Ives, Francis J., Assistant Surgeon, July 25, 1890. To be assistant surgeon with the rank of captain, after five years' service, in accordance with the act of June 23, 1874. Headquarters of the Army, A. G. O., Washington, August 11, 1890.

Kendall, William P., First Lieutenant and Assistant Surgeon, to be assistant surgeon with rank of captain, after five years' service, from August 12, 1890. Headquarters of the Army, A. G. O., Washington, August 18, 1890.

Reed, Walter, Captain and Assistant Surgeon, is, with the approval of the Acting Secretary of War, granted leave of absence for four months, to take effect about September 1, 1890. Par. 17, S. O. 192, A. G. O., Washington, D. C., August 18, 1890.

By direction of the Acting Secretary of War, a board of medical officers, to consist of Middleton, Joseph V. D., Major and Surgeon; Ewen, Clarence, Major and Surgeon; Hopkins, William E., Captain and Assistant Surgeon, will assemble at the U. S. Military Academy, West Point, N. Y., at 11 o'clock, A. M., August 27, 1890, or as soon thereafter as practicable, to examine into the physical qualifications of the candidates for admission to the Academy. Par 1, S. O. 192, Washington, D. C., A. G. O., August 18, 1890.

Mason, Charles F., First Lieutenant and Assistant Surgeon, is, by direction of the Acting Secretary of War, relieved from further temporary duty at Fort Logan, Colorado, and will report for duty at his proper station (Fort Washakie, Wyoming). Par. 3, S. O. 191, A. G. O., Washington, D. C., August 16, 1890.

By direction of the Acting Secretary of War, the retirement from active service this date, by operation of law, of Moore, John, Brigadier-General and Surgeon-General, under the provisions of the act of

Congress approved June 30, 1882, is announced. General Moore will repair to his home, Bloomington, Indiana. Par. 2, S. O. 191, A. G. O., Washington, D. C., August 16, 1890.

McCreery, George, Captain and Assistant Surgeon. The leave of absence for seven days, granted by Orders No. 84, Fort Warren, Massachusetts, August 13, 1890, is hereby extended fifteen days. S. O. 193, Headquarters Division of the Atlantic, Governor's Island, New York city, August 15, 1890.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of April 23, 1890.

The President, Dr. C. K. Briddon, in the Chair.

Removal of Diseased Appendices.—Dr. L. A. Stimson detailed the histories of several cases of appendicitis in which he had recently operated, and presented the diseased organs removed.

The first case was that of a young man from Middletown, N. Y. This patient had suffered from four attacks within a year, the last one about six weeks before the operation. The history was clearly that of appendicitis, and the second and fourth attacks had not been quite so severe as the first and third. The usual incision was made and the appendix exposed. It was lying free in the abdominal cavity, its base being directed forward and in contact with the anterior abdominal wall, so that it presented in the wound. The apex of the organ, which he exhibited, was adherent to the omentum and slightly so to the cæcum. It was dissected out from the mesentery, ligated with catgut close to its origin, and removed. The case was a typical one. The wound had healed almost without suppuration within three weeks, and the patient had only remained in the city in order that he might be presented to the society. Dr. Ferguson, pathologist to the New York Hospital, had examined the appendix after removal, and had found that its mucous membrane was entirely destroyed by catarrhal inflammatory process. There was no pus or foreign body within its cavity. The muscular coat of the organ was thickened and infiltrated with round cells.

The second case was that of a patient, sixteen years old, whom the records of the hospital described as having been three years previously under treatment for general periton tis due to trauma. Since that time the lad had suffered from many attacks of pain in the right iliac fossa. When seen on admission to the hospital, about two weeks before the meeting, he had come complaining of a pain in his abdomen of ever-increasing severity. There was a temperature of 102° F., and there was marked tenderness in the right iliac region. The operation revealed the appendix as occupying a similar position to that in the previous case. The distal end was directed forward and was in contact with the anterior abdominal wall. The cæcum was above it, while a small pocket was found formed by the adhesion of a knot of small intestines to the cæcum and the abdominal parietes, and within this the appendix lay. This made the dissection quite difficult, and there was free bleeding. After dissecting out about two inches of the appendix and ligating it with catgut it was cut away, and there escaped from its cavity about a drachm of turbid, non-purulent liquid. The interior of the appendix was deeply congested and seemed to be in a sloughing condition. At the apex the wall of the organ was reduced to a thin membrane and seemed to be on the point of rupturing. A slight amount of turbid fluid was found free in the abdominal cavity. This patient had made a rapid and uneventful recovery.

The third specimen presented was that of an appendix taken post mortem from a man who had been brought into the hospital in a moribund condition. The patient was a Norwegian, thirty years of age. He gave a history of previous attacks of peritonitis. His abdomen was distended, his temperature 104°, and his general appearance that of a man about to die. There had been no movement of the bowels since this last attack came on, nearly a week before. The case was clearly one in which operative interference would be useless; indeed, the speaker had some doubt as to the real character of the trouble. An artificial anus was made with the view of relieving the distention. The man died, and upon removing the appendix it was found to present an appearance similar to that in the other two cases. There was no foreign body within it, but its mucous membrane was found to be in a condition of catarrhal inflammation. The abdominal viscera were in a state of general peritonitis without exudation.

The speaker narrated as a fourth case that of a physician of this city who had suffered five previous attacks within three years, each of which was said to have been cut short by a dose of castor-oil. The last attack had commenced on Thursday, three weeks before. The speaker had seen the case first on Friday, at which time the patient had described himself as getting well fast. On the following Sunday, however, he had come to the New York Hospital and sent for the speaker, stating that he had felt something give way in the abdomen, and this was followed by great rectal tenesmus. Introduction of the finger revealed a soft mass depressing the anterior rectal wall behind the bladder. There was tenderness in the right iliac fossa, together with some resistance on deep pressure. Aspiration of the mass pressing upon the rectum with an exploring needle revealed the presence of fœtid pus. The sphincter was then stretched and the abscess opened through the rectum. This was found to be in the peritoneal cavity and behind the bladder, the latter fact being ascertained with a sound in the bladder. Evacuation of the abscess contents was followed by a rapid fall in the patient's temperature and such general improvement that in a few days he was able to leave the hospital.

The speaker said he had presented these four cases because he thought they all represented instances of catarrhal inflammation of the appendix with non-perforation, and had all been of the recurrent type. In one case it had been demonstrated that non-perforative appendicitis was capable of destroying life, while another had shown that an abscess of considerable size might form and rupture in such a way that its contents would determine to the lower part of the abdominal cavity. The conditions in each case had been such that the patients might well have died. He thought that when, on the one hand, one considered the excellent results that had thus far followed the removal of the diseased appendices through the abdominal cavity, and, on the other, the very dangerous character of the processes to which these inflammations could give rise, one was justified in advocating early operative interference.

Suprapubic Lithotomy.—Dr. A. J. McCosh presented a patient from whose bladder he had removed nine calculi weighing in all four hundred and sixty grains. The wound in the bladder had been about an inch in length and through this the stones had been removed. This opening had then been sewed up, except a slit left for a drainage-tube. A perineal opening was then made, and after some difficulty, on account of an enlarged prostate, a tube was introduced into the bladder for perineal drainage. Some trouble had been caused by occlusion of this latter tube by mucus during the first few days, and during this time the urine had come entirely through the suprapubic

opening. A large perineal tube was introduced and perfect drainage thereby established. Thirteen days after the operation the suprapubic wound had closed. The perineal wound was now almost healed, and most of the urine now came through the penis. The speaker had reported the case to emphasize his appreciation of the advantages of the perineal opening. It had been very noticeable that whenever the drainage through the perineal opening was insufficient and the urine was forced to find outlet through the suprapubic incision, the patient's general condition had changed for the worse. His temperature went up a degree or more, his pulse increased in frequency, and his appetite failed. When the perineal drainage was re-established, the man became himself again. The speaker was much impressed with the result, and in operating upon other old patients, this one being seventy-two years of age, he should certainly make the perineal opening, while in younger ones he would also favor this opening and the suturing of the bladder wound as recently advocated before the society by Dr. McBurney.

Recurrent Appendicitis.—Dr. J. A. Wyeth presented a patient, sixteen years old, who had been sent to him by Dr. Ground, with the following history: The first trouble had begun in June, 1887, when he had vomiting and felt severe pain in the right iliac fossa. Previous to this attack his bowels had been regular. The attack lasted very nearly two days and was attended with no fever. About two months later he had his second attack, when he experienced symptoms similar to those present in the first one. The third attack occurred in January, 1888, and was quite severe. The greatest amount of pain was midway between the umbilicus and the right anterior superior spinous process. The temperature in this third attack ran as high as 103° F., and a tumor was found in the right iliac fossa which was quite firm. This attack had lasted about two weeks. In May, 1888, he had his fourth attack, which was the severest of all, the vomiting and abdominal pains being very distressing. About the fifth day a tumor was found in the right inguinal fossa. Peritonitis had then developed and extended over a considerable portion of the abdomen. There was marked tympanites and the temperature ran as high as 104°. In this attack he failed rapidly and had chills, and about the twelfth day the tumor was aspirated and some pus was obtained. This fourth attack lasted four weeks. Up to the time of his entering the Polyclinic Hospital, in February, 1890, he had had sixteen attacks, which had recurred at intervals of a month or two and were similar to those already described. During the attacks he was constipated, but in the intervals his bowels were regular and his appetite was good. Vomiting was present in almost every attack and a tumor of pronounced character was to be made out in about half of the attacks, but when it was absent a marked sense of resistance could be noticed.

On March 11th, while in the hospital being prepared for an operation, he had another attack, which lasted about a week and caused the operation to be postponed.

On March 27th the boy was operated on by the speaker. Considerable difficulty was experienced in finding the appendix, on account of extensive adhesions. At last a very small, firm appendix was found, about two inches in length and of about the diameter of the little finger. It was adherent to the peritonæum and was bound down beneath and parallel with the iliac artery. It was tied off and found to contain no foreign body. Although the boy had had sixteen attacks of localized peritonitis, there did not seem to be any active inflammation present, but the appearance was that of a catarrhal condition. The speaker was by no means certain that the appendix had been alone responsible for the trouble. The patient had made an uninterrupted recovery and was now quite restored to a condition of normal good health.

Dr. Robert Abbe asked if there had been any relief in Dr. Stimson's case where an opening had been made to lessen the pain of pressure by gas. He understood that the gas liberated was only for a distance of twelve inches from the point of the pain.

Dr. Stimson replied that there had been an immediate and abundant discharge of fæces through the opening.

Dr. Wyeth mentioned a case in which the patient was in a moribund condition from obstruction. To relieve the distention he had opened the abdominal cavity, taken the first loop of intestine that presented, and cut a hole in it. There had been a copious discharge of gas, the patient had begun to breathe, the obstruction was removed, and the woman had recovered.

The President mentioned a case in which laparotomy was done for a wound of a large artery in the abdominal cavity, and in which there was paresis of the intestinal canal. In the search for the vessel almost all the intestines were turned out of the abdominal cavity. They were bound and bunched together by the exudations of a former peritonitis and dilated to their fullest extent. He had found it necessary to make four or five short incisions at various points before he could reduce them. Of course, these incisions were sutured when the gases had escaped.

Dr. J. D. Bryant said that, although the fact appeared to be well established that the escape of gas in these cases was somewhat limited, he would add two more cases in support of that fact. In these cases a small aspirating needle was passed obliquely through the intestinal wall. Only a limited portion of the intestine was emptied of gas, and that mainly by the influence of external pressure on the intestine at either side of the point of puncture. In one of these cases great difficulty was experienced in closing the puncture properly with sutures. The speaker's experience thus far led him to consider intestinal puncture under these circumstances as of doubtful expediency from all standpoints.

Dr. Wyeth, in reply to a question by Dr. Murray, said he had not operated in his case of appendicitis during the acute stage of the sixteenth attack, as the boy had already recovered from all the previous ones, and he thought it advisable under the circumstances to let him alone rather than risk interference in the acute stage.

Paranephric Cysts.—Dr. R. Abbe read a paper with this title. (See page 147.)

Dr. Stimson referred to a case which seemed analogous to those of Dr. Abbe's. The patient, a man, had a large tumor apparently connected with the left kidney. This was reduced by multiple aspirations, three in all being made in the course of six weeks. Since that time there had been no return of the fluid.

Ovarian Fibroid and Tubal Pregnancy.—Dr. McCosh narrated the case of a woman admitted into the Presbyterian Hospital with the following history: She had always menstruated irregularly, both profusely and painfully, and for many years her periods had been delayed or were too frequent, interchangeably. She had been married two years and had never been pregnant to her knowledge. Five months ago her periods had ceased altogether and had not recurred. For fifteen years she had had abdominal pain and tenderness, with bearing-down sensations, especially at her menstrual epochs. Seven years ago she had noticed a swelling in the right side, appearing after severe exertion. It had seemed larger during menstruation. Five months ago a swelling on the left side appeared which grew rapidly, and menstruation had ceased. According to the patient's observations, there were no breast changes. She had lost flesh and strength.

Examination revealed a solid tumor growing out of the pelvis and occupying the middle of the abdomen as high as the umbilicus. On the left side, at a point on a level with and above the umbilicus, there was felt a fluctuating tumor adherent to or forming a part of the mass just mentioned. The diagnosis was made of uterine fibroid complicated by a cyst. On opening the abdomen, the body of the uterus was found occupied by a fibromyoma somewhat larger than an adult head. Springing from near its upper border on the left side was a thin-walled cyst almost as large as the solid tumor, to which it was closely adherent. At the time the speaker thought that it might be a tubal gestation-sac. Even subsequently, on opening the sac, which contained a four-and-a-half-months fœtus, he could not tell whether it was a Fallopian tube or the left cornu of the uterus. On account of a firm adhesion of the sigmoid flexure to the upper part of the cervix uteri, it was deemed best not to remove the entire uterus, and hence the pedicle was fastened in the abdominal wound. The patient made an uninterrupted recovery. An examination of the tumor showed that the entire body of the uterus was occupied by a fibromyoma, and after shrinkage of the fœtal sac it was evident that it was the dilated left uterine cornu. The uterine canal could not be traced higher than the internal os, and careful dissection failed to find any communication between this canal and the sac in which the fœtus lay. It was evident that delivery *per vias naturales* would have been impossible, and that, had the patient been allowed to go to term without rupture taking place, a Porro operation must have resulted.

The pathologist's description of the mass removed was as follows: A nearly spherical mass about 5 inches in diameter, very firm and resembling a fibroid: on section, for the most part white, over a considerable portion a grayish discoloration. About one third of its surface is covered with peritonæum. Attached to this tumor, over an area about 4 inches in diameter, is a second mass, hollow, with a cavity about 3 inches in diameter, with a smooth lining, pinkish gray, and showing some yellowish patches resembling atheromatous tissue; walls about 1 inch thick, resembling loose uterine tissue. It is covered externally by peritonæum, has a pedunculated fibroid attached to it 1 inch in diameter, also the left tube and ovary and the beginning of the right tube. Inside this cavity, which has been opened, all along one side is a fœtus 4¼ inches long, from vertex to tuber ischii, with its membranes, cord, and placenta. The left ovary shows a corpus luteum ½ inch in its longest diameter. The ovary is 1¼ inch long, somewhat fibrous, and contains several minute cysts. The whole tumor, without the fœtus, weighs 5 pounds.

Osteo-chondromata.—Dr. A. G. Gerster presented two specimens of this condition taken from two patients in whom the clinical histories were for the most part similar. The first specimen had been removed from the right popliteal space of a woman between thirty and forty years of age, where it had existed for many years as a painless tumor, causing no inconvenience except that it had impeded the function of the joint. Six weeks before she had come under the speaker's notice, sharp, shooting pains had commenced along the course of the popliteal nerve. The tumor was apparently attached to the lower end of the femur near the epiphyseal line, and projected backward and inward. It had seemed to be pedunculated. The vessels and nerves were displaced outward. He had told the patient that he could not be positive as to the exact nature of the growth. His diagnosis had been either osteo-chondroma or sarcoma of the lower end of the epiphysis of the femur. On cutting down, he had found the growth invested by a membrane resembling periosteum. Keeping well out of the way of the vessels and nerves, he was able to expose the pedicle of the growth and to remove the mass easily with a chisel and mallet. The patient had made an uneventful recovery.

The second and larger specimen had been removed from a young man twenty-one years of age. The general details of the case were in effect similar to those of the previous case. The speaker would remind the meeting of the ease with which this operation could now be undertaken as compared with fourteen years ago. Then a small incision was made and a chain-saw used. Now, by ample incision and the use of the chisel, there was no difficulty and no danger of lacerating the surrounding tissues.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

SECTION IN OBSTETRICS.

Meeting of May 23, 1890.

The President, Mr. S. R. Mason, in the Chair.

Fibromyoma of the Ovary.—Dr. Bagot showed a fibromyoma of the ovary, and stated that the tumor was of great interest and importance from a pathological point of view, because there seemed to exist a great difference of opinion as to the nature of that rare class of tumor—namely, the solid non-malignant tumors of the ovary. Some observers stated that they were fibromata, others that they were chiefly fibromyomata. Spencer Wells had met with but six examples, which he considered to be fibromata. Dr. Alban Doran, however, in his book on *Tumors of the Ovary, Fallopian Tube, and Broad Ligament*, published in 1884, stated that he had examined one of these tumors, which had been presented by Spencer Wells to the museum of the Royal College of Surgeons, London, and that it was a leiomyoma, containing but little true connective tissue. All the solid tumors that he himself had seen, removed at operations, were either carcinomata or sarcomata. Olshausen had described them as consisting of connective tissue, sometimes with a few muscular fibers; but the latter were always scanty. Martin agreed with him. Winkel stated that they were chiefly connective-tissue growths. Waldeyer found no trace of smooth muscular tissue. Leopold and Wyder's observations coincided with Waldeyer's, but Klebs and Tücke found muscular tissue, as did also Hartmann and Terrier.

Dr. Bagot's case was as follows: J. D., aged forty-four years, married twenty years, had given birth to eight children. Eight years had elapsed since her last pregnancy. In December, 1889, she came to the Rotunda Hospital to have a pessary changed, as she had been wearing it for some time. The following conditions were found on examination: Perineal laceration of the first degree; the external os patulous; the cervix fissured; slight ectropion; the uterus normal in size; the fundus retroverted toward the left; the left ovary normal. There was a tumor of the right ovary, somewhat larger than a walnut. Nothing else abnormal could be made out. The woman had been in bad health and was complaining of various nervous symptoms, but, as none of these could be distinctly traced to the ovary, and as it did not seem to be injuring her in any way, it was not interfered with. The patient had been under Dr. Macan's care since 1884, when the same diagnosis and prognosis had evidently been adopted. In March, 1890, however, the tumor was very much larger, and, as it grew so rapidly, it was thought advisable to remove it. Accordingly, on March 27, 1890, the speaker removed it by an abdominal section. The patient made a perfect recovery, and all her former symptoms disappeared.

Dr. Earl had kindly made a microscopical examination of the tumor and found the following: The tumor consisted mainly of unstriped muscle, arranged in bundles. Adjoining bundle-

ran at right angles to one another. Traversing this tissue were numerous tracts of fibrous connective tissue, rather dense. They presented a somewbat insular appearance as seen in the sections. Small blood-vessels could be seen here and there, and there appeared to be very tbick external coats to these vessels.

Observations on a New Speculum Illuminator.—Dr. T. More Madden said that the importance of sufficient illumination as an essential element in the diagnosis and treatment of the various morbid conditions of tbe vaginal portion of the uterus or of the vagina in which tbe speculum was resorted to was obvious. And yet to the neglect of due attention to tbis consideration must be largely ascribed some of the erroneous views and practices whicb for many years had retarded the progress of gynæcology. This point he illustrated by a reference to the very opposite opinions at different periods held by authorities of equal accuracy and of equal experience with regard to the aspect and character of the most common forms of disease discernible through the vaginal speculum. Had, however, those who tbus differed as to the nature and treatment of the pathological conditions presented to visual examination by the speculum possessed instruments such as those now available for this purpose, and enjoyed the advantage of the methods of illumination by whicb, when necessary, the best of all ligbts—namely, that of direct sunlight—might be replaced, the heated controversies and fallacious practices of former days might probably have been avoided. Much as had been done in this way, there still remained, however, some room for further improvement, as even yet, among the every-day troubles of gynæcological work, not the least frequent or least annoying of its kind was the difficulty occasionally experienced in making a satisfactory visual examination of the vagina or vaginal portion of the uterus in many cases where it was required for diagnostic or therapeutic purposes. In regions wherein sunshine was so exceptional as was unfortunately the case under the leaden skies and murky atmosphere of the British Isles, this difficulty frequently presented itself even in the physician's best-arranged consulting room, where the couch was most advantageously placed with reference to light. And, *a fortiori*, it occurred still more commonly in the patient's chamber, where the bed was often so situated as to preclude full access of natural light into the speculum. And, in his opinion, the deficiency was not supplied by any of the electric lamps which, so far at least, he had himself employed. These, he had found, were apt to fail at the moment their assistance was needed, as, owing to some one or other of the defects, either in battery, connections, or lamp, that were of such frequent occurrence in electrical apparatus, on pressing the button, instead of the brilliant flood of electric light expected, the result obtained might be either *nil* or else merely the dull-red glow of the incandescent carbon filament. On the other hand, if we contented ourselves with the more reliable if less elegant "bit of candle end," still recommended by some authorities, the necessity for holding it so as to throw some light into the speculum must interfere with any manipulation required by tbe case. Therefore the speaker desired to suggest to other practitioners who were likely to meet witb the difficulty he had often thus encountered, a trial of the little contrivance now exhibited, which he had found serviceable under sucb circumstances. This consisted of a very portable, many-jointed illuminator, capable of rotation in every possible direction, which could be instantly and securely affixed to any form of speculum, so as not to be in the surgeon's way, while affording sufficient and reliable light for all examinations or operations in the vaginal passage. This instrument, he added, had been very carefully made, in accordance with his directions, by Messrs. Lynch & Co., Aldersgate Street, London.

Dr. MoVeigh was of opinion that the illuminator would prove of the greatest use, especially in making examinations in the evening.

Dr. Macan remarked that probably every gynæcologist had his own plan for getting through his work in the dark. For his own part, he did not find any difficulty in working with an ordinary lamp and reflector; and he did not know tbat the instrument now exhibited would prove much better. He had also used the ordinary electric light; but the objection to it was that the operator had to use one hand in holding it, while he manipulated witb the other. He had not found any difficulty in working with an ordinary gas lamp. He was sure that the present instrument was a very capable one, but he did not think it a necessity.

Dr. Byrne said he considered Dr. Madden's invention very ingenious and simple.

Dr. Bagot said tbe present instrument was liable to the same fault that existed in the case of others also, namely, that the light was between the operator and his work. For the purpose of an operation he thought that a lamp or electric light, with a reflector on the forehead, would be more effectual and less in the way.

Dr. Madden said he had found this instrument useful not only in cases in the hospital with which he was connected, but still more so in private practice, inasmuch as some of the electric and other lights relied on for utero-vaginal examinations were very troublesome to carry about, and were apt to go out at a moment's notice.

SECTION IN PATHOLOGY.

Meeting of May 30, 1890.

The President, Dr. E. H. Bennett, in the Chair.

Porencephaly.—Dr. Conolly Norman read a paper on porencephaly. He briefly traced the history of this affection in medical literature from the days of Heschl, who first described it under this name, to Andry, who had recently written a valuable memoir. Dr. Norman described a case which had occurred in his own practice. The patient was not an idiot. The history was very defective, but he was known to have been a criminal. When under Dr. Norman's care he suffered from paranoia, with persecutory delusions. He exhibited partial right hemiplegia without aphasia. He died of pbthisis. Tbe brain showed a large opening on the left side leading directly into the lateral ventricle, the insula, the operculum, and the internal capsule being absent. The optic thalamus and optic tract on the left side were diminutive. Having described the conditions found in some detail, and exhibited some beautiful photographs of the brain made by Professor Fraser, Dr. Norman dwelt upon the various theories of the causation of porencephaly. He inclined to believe that a case like this was probably a condition of arrested development, and regarded the membrane which closed the opening in these cases as the altered wall of the secondary anterior cerebral vesicle which bad not developed nervous matter. The most interesting points were: 1. The ætiology. 2. How the functions of the internal capsule were even imperfectly performed in the absence of that structure.

Dr. C. J. Nixon remarked that Dr. Norman had discussed porencephaly as if it invariably had a congenital origin; but it was equally true that porencephaly was acquired; for instance, from injuries several montbs after birth, or from acute, exhausting diarrhœa, or from a bad form of measles or scarlatina, resulting in infantile hemiplegia or in total paralysis.

Dr. T. Myles said the photograph shown by Dr. Norman seemed to be one of the brain of an orang-outang or of a South African bushman rather than of an ordinary human brain; for the Sylvian fissure, instead of being horizontal, was nearly ver-

tical; the fissure of Rolando was invisible; the parieto-occipital fissure extended to the temporo-sphenoidal bone, and the tip of that bone, instead of reaching out to the frontal lobe, was undeveloped, extending only as far as the Sylvian fissure.

Dr. Norman said the conditions described by Dr. Myles were attributable to the fact that the brain had been allowed to lie a little crooked and was badly hardened; but the fissure of Rolando was specially marked and recognizable, while the temporo-sphenoidal lobe had got squeezed up. There was no trace of destruction of tissue or of any lesion from thrombosis or other cause. The chief problem was, from what had taken place to the fibers of the internal capsule, how any movement remained in the limbs, which were entirely cut off from what were regarded as the motor centers of the cerebral cortex.

Dr. Nixon asked if there was volitional movement in the limbs, notwithstanding the destruction or absence of the internal capsule.

Dr. Norman said there was volitional movement, limited in extent and impaired, but undoubtedly existent.

NEW NASO-PHARYNGEAL SCISSORS.

By F. C. Raynor, M. D.,

ASSISTANT SURGEON TO SKIN AND THROAT DEPARTMENT, BROOKLYN EYE AND EAR HOSPITAL.

The instrument which is illustrated herewith was designed for the removal of adenoid vegetations from the vault of the pharynx by substituting a clean cut for the older and more common methods of crushing, scraping, and tearing, and, as it has proved so satisfactory in my hands and in those of others to whom I have submitted it for trial, I venture to bring it before the profession. It is believed to be the only instrument for this purpose working on scissors principle, all other cutting instruments with which I am familiar being variously formed punches. Its shape can be well appreciated by referring to the cuts. *a* representing the instrument closed, *b* open for use. Its form in general resembles the letter *f*, the female blade terminating in a rounded point, the male blade being prolonged to make a fenestra for bringing away the portion excised. In size it corresponds closely with

Hooper's forceps, and is therefore adapted for use in small children As the cutting surface extends from the joint to the tip of the female blade, it may be employed for removing hypertrophied follicles from the posterior pharyngeal wall, trimming ragged tonsils, etc. The

instrument, being small and delicately made, should only be used in operating on soft tissues. Both Dr. Sherwell and myself have operated without general or local anæsthesia, and the pain produced was very slight. The instrument was made for me by George Tiemann & Co.

169 State Street.

Miscellany.

The American Orthopædic Association will hold its fourth annual meeting at the College of Physicians, Philadelphia, on Tuesday, Wednesday, and Thursday, September 16th, 17th, and 18th, under the presidency of Dr. DeForest Willard, of Philadelphia. The programme includes the following papers: Spinal Distortions and their Treatment by the Straightened Leather Jacket, by Dr. Bernard Bartow, of Buffalo; Treatment of Deformities of Spastic Paralysis, by Dr. E. H. Bradford, of Boston; Tenotomy for Relief of Deformity in Spastic Paralysis, by Dr. Arthur J. Gillette, of St. Paul; Amputation as an Orthopædic Measure, by Dr. Ap Morgan Vance, of Louisville; A Ready Method of Counter-traction of the Knee, by Dr. Henry Ling Taylor, of New York; Treatment of Infantile Club-foot preliminary to Operation, by Dr. F. H. Milliken, of New York; Paralytic Club-foot, by Dr. W. R. Townsend, of New York; Ten Years' Experience in the Management of Knee-joint Disease, by Dr. V. P. Gibney, of New York; The Inefficiency of Mechanical Treatment in Spasmodic Wryneck, with a Report of Three Cases, by Dr. G. W. Ryan, of Cincinnati; Sacro-iliac Disease, by Dr. Benjamin Lee, of Philadelphia; Instantaneous Photograph, illustrating the Gait of a Child from whom both Hips had been removed, by Dr. H. M. Sherman, of San Francisco; a discussion on the subject of Rotary Lateral Curvature of the Spine, in which the following papers will be read: The Nervous and Muscular Elements in the Causation of Idiopathie Curvature, by Dr. Benjamin Lee; the Muscular Element in the Ætiology, by Dr. Charles L. Scudder; Ætiology, by Dr. R. W. Lovett; Mechanism of Rotation, by Dr. A. B. Judson; the Mechanical Theory, by Dr. O. H. Allis; Causes, by Dr. M. T. Bissel; Pathogeny, by Dr. Newton M. Shaffer; Treatment especially Applicable to Poor and Dispensary Patients, by Dr. V. P. Gibney, and papers on Treatment by Dr. E. H. Bradford, Dr. B. E. McKenzie, and Dr. Henry Ling Taylor; The Significance and Value of Involuntary Muscular Protection and the Limp of the First Apparent Stage of Hip Disease, by Dr. Newton M. Shaffer; Treatment of Hip Disease, by Dr. B. E. McKenzie, of Toronto; A Report of Sixty-two Cases of Hip Disease observed in the Practice of Hugh Owen Thomas, by Dr. John Ridlon, of New York; Diseases of the Eye associated with Spinal Caries, by Dr. James K. Young, of Philadelphia; Posterior Rhachitic Curvature of the Spine, by Dr. Samuel Ketch, of New York; Lateral Deviation of the Spinal Column in Pott's Disease, by Dr. R. W. Lovett, of Boston; Relief of Paraplegia, by Dr. A. J. Steele, of St. Louis; Prognosis of Pressure Paralysis, by Dr. T. Halsted Myers, of New York; Do Orthopædic Surgeons operate as frequently as they should? by Dr. J. E. Moore, of Minneapolis; Joint Diseases, by Dr. John Ridlon, of New York; aud papers by Dr. T. G. Moton, Dr. Roswell Park, Dr. R. H. Sayre, and Dr. H. A. Wilson.

Sulphurous Disinfection.—Dr. Henry B. Baker, Secretary of the Michigan State Board of Health, has addressed a letter to Dr. E. B. Frazer, Secretary of the State Board of Health of Delaware, of which the following is a copy:

Dear Doctor: Your letter of August 18th, acknowledging the receipt of a copy of my letter to Dr. Dufficld (giving results of experience of health officers in Michigan, and an account of experiments by Pasteur, Roux, Dujardin-Beaumetz, and others relative to sulphurous disinfection), is before me. You ask me for further opinion, and refer to the *Report of the Maine State Board of Health* for 1889, page 251, and Dr. T. Mitchell Prudden's estimate of the want of value of sulphurous disinfection.*

There are at least two valid objections to the acceptance of Dr. Prudden's conclusions to which you refer: 1. His experiments dealt with a micro-organism which seems to be different from the one most generally accepted as the probable cause of diphtheria. Therefore he may or may not have been dealing with a micro-organism causing diphtheria. 2. The quantity of sulphur burned, the strength of the sulphurous-acid fumes which he employed, is not stated. It having been proved by actual experience with disease, and by other laboratory experimenters (Pasteur, Roux, Dujardin-Beaumetz, Vallin, Legouest, Polli, Pettenkofer, Dougall, Fatio, Pietra Santa), that sulphurous-acid gas is not always a disinfectant when employed in small proportions, and that it is a disinfectant when employed in large proportions, such as result from the burning of three pounds of sulphur to each thousand cubic feet of air-space, no different conclusion should be reached from Dr. Prudden's experiments as published.†

You mention that Dr. W. H. Welch, of Baltimore, "enters his protest against" disinfection by sulphurous-acid gas. I respectfully submit that entering a protest should count for very little in science as against results of actual practical experience in the restriction of diphtheria; it should not even take rank with definite statements of results of laboratory experiments.

Laboratory experiments are very valuable, but they need to be repeated, by the same observer and by other observers, in order to eliminate errors due to accidental and incidental conditions.

It is not easy to make laboratory experiments which shall conform to or correctly represent average conditions in actual outbreaks of disease. That is probably one reason for the discrepancies in laboratory experiments, and for the disagreement of some laboratory experiments with practical experience with disease. One reason for this last disagreement may be that micro-organisms which, after subjection to a disinfectant, may yet have sufficient vitality to reproduce in a laboratory where the most favorable conditions are supplied, could not possibly do so in the human throat, or elsewhere in the human body, because of the well-known power of the fluids of the body to destroy micro-organisms, as proved by Dr. Prudden's and other laboratory experiments following, but not confirming, Metschnikoff's doctrine of the phagocytes.

Progress would be easier, more rapid, and the backward and forward movements less frequent, if experimenters in laboratories would be more careful in stating the details of their work.

The interpretation of the results of laboratory experiments and the determination of the bearing which they should have upon practical affairs is an extremely difficult work, and one in which there is very great liability to error.

Practical health officers need to employ a gaseous disinfectant that shall at once reach all surfaces, ledges, cracks, drawers, and receptacles of dust wherever it may be in a room, that shall permeate all articles sufficiently permeable to admit disease-causing micro-organisms, that will not necessitate too much labor in the removal of furniture or other articles, and that shall have power to destroy or sufficiently weaken the vitality of the "germs" of such diseases as diphtheria and scarlet fever, and occasionally small-pox, as they are usually distributed in the sick-room, and that shall not destroy family portraits and similar arti-

† *Ibid.*

cles. Only two such disinfectants are prominently before us for choice —chlorine and sulphurous-acid gas. Of these two, sulphurous-acid gas is made, in proper quantity, with more certainty and less trouble than is chlorine gas; and at present I regard the weight of evidence in its favor as equal to that relative to chlorine gas, concerning which not so much evidence has been published. Practical experience in Michigan proves that by isolation of first cases of diphtheria, and disinfection of premises after death or recovery therefrom by fumes of burning sulphur, etc., four fifths of the cases and deaths which would otherwise occur from that disease are prevented. If there is any other method of disinfection or any other procedure that can be shown to reduce the cases and deaths more than the four fifths and down to less than an average of two and one third cases and six tenths of one death to each outbreak, I am exceedingly desirous of knowing what it is. But, inasmuch as that is the recent experience in Michigan (outside of the great cities), it does not seem best to give up the methods employed until evidence of a better method is produced.

Meantime I would advise a continuance of sulphurous disinfection, for the purposes for which it is applicable, and for which it is greatly needed as stated above, not including the disiufection of excretions from the patient, for which chlorinated lime or liquid is applicable, nor of bits of diphtheritic membrane, which should be destroyed by fire, as should also all rags and everything else not too valuable used about a patient; and all clothing, bed-clothes, etc., that can profitably be boiled should be so treated.

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for August 22d:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—									
				Cholera.	Yellow fever.	Small-pox.	Varioloid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.

Successful Operation for Actinomycosis.—"Dr. Matlakowski, of Warsaw, reports an interesting case of actinomycosis in a man which was successfully eradicated by operative measures. The patient, who was engaged in agricultural pursuits, was forty-six years of age, and had noticed for six weeks a rounded, movable tumor, which did not cause him any pain, under the angle of the jaw on the right side. He had been losing the teeth for the last fourteen years, they having fallen out without being carious. The last tooth in the right lower jaw had fallen out a year before. The tumor kept on increasing, and a week before admission a small abscess had broken. Not only was there no pain, but there was no difficulty in opening the mouth or in swallowing. When first examined there were two fistulous openings near the angle of the jaw, but a probe passed into them did not penetrate at all deeply, and could not be made to reach the bone; a considerable quantity of blood exuded in consequence of the probing. The discharge was scanty and looked like boiled sago mingled with bloody serum. The molars and canines were all wanting in the lower jaw on the affected side, the gum, which was healthy enough, having grown over their alveoli. The ray fungus having been found on microscopical examination, and there being a complete absence of any signs of disease elsewhere, an operation was decided on. Ample incisions having been made, parts of the masseter, digastric and sternomastoid, and the whole of the mylo-hyoid muscles were excised, together with the entire submaxillary gland and the lower part of the parotid, also the bridge of salivary gland substance connecting the two glands. A large number of arteries and veins had to be ligatured. At first the patient experienced some difficulty in swallowing, and in expectorating a quantity of tenacious and somewhat sanguinolent mucus, for the existence of which no physical cause could be found by examination of the lungs. However, after a time all these difficulties passed off, and the wound, which was, of course, a large gaping cavity in consequence of the quantity of tissue that had been extirpated, granulated up and healed over. Two years and a half afterward Dr. Matlakowski obtained information that the patient continued in good health."—*Lancet.*

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

BY JAMES K. CROOK, M. D.,
INSTRUCTOR IN CLINICAL MEDICINE AND PHYSICAL DIAGNOSIS, ETC.

LECTURE II.

Bronchial Asthma.—We have to-day, gentlemen, several patients with chest trouble who complain principally of one symptom—viz., shortness of breath. Ask any one of these what he or she is suffering from, and the answer will probably be "asthma." To the laity all these troubles involving difficulty of breathing are known by that name. This was formerly true among physicians also, until the researches of pathology taught us the vastly different conditions which produce this symptom. On investigation, we find that only one of these cases is entitled to the name of asthma as we understand it at the present day. Patient No. 1 has a well-marked case of mitral regurgitation; No. 2 has dropsy of the lower extremities and ascites, with a dilated heart, and probably is in an advanced stage of Bright's disease; No. 3 is suffering from chronic pleurisy with a moderate effusion; No. 4 is a case of pronounced emphysema; while No. 5 is undoubtedly a *bona-fide* case of spasmodic bronchial asthma. The patient is a stout old woman of seventy, and she informs us that she has a cough almost all the year round, being worse in the winter months. Sometimes it will cease for a little while during the summer. Her breathing, as you will see, is perfectly free and easy at present, but she states that several times during the week, and often when in bed, she is seized with a severe spell of shortness of breath. During the attacks she is obliged to sit perfectly quiet by an open window and in a position leaning forward. A loud wheezing occurs, which may be heard all over the room. The spells last from a few minutes to several hours. Last night she had an unusually severe seizure, which extended over most of the night. She has some shortness of breath also whenever she takes unusual exercise, but it is not attended by wheezing, and may be due to her stoutness and advanced age. On physical examination we find no signs except an occasional moist râle. If we could see the patient during a paroxysm of dyspnœa we should undoubtedly find a large number of sibilant and sonorous râles on auscultation, with probably a great prolongation of the expiration. We have here, then, a very well marked case of asthma attended by bronchitis. Beyond the slight lesions produced by the latter trouble there are no anatomical lesions in this disease. It is essentially a neurosis—according to Biermer, whose classical definition is commonly accepted, a neurosis depending upon tonic spasm of the bronchial muscles and caused by faulty innervation of the pneumogastric nerve. It is probable that during the seizures the bronchial membrane is very much congested from distention of the small vessels in the bronchial walls. This has, in fact, been proved by the tracheoscopic researches of Stoerck, and has been said by Theodor Weber and others to be the true anatomical basis of the disease. Some authorities, led by Wintrich, maintain that there is no spasm of the bronchial tubes during the attacks, but a spasmodic fixation of the diaphragm and other muscles of respiration. The fact of bronchial contraction, however, is abundantly shown by the presence of sibilant and sonorous râles and loud wheezing. There are even other theories of the pathology of asthma, but that of Biermer before mentioned is most satisfactory. The asthma crystals discovered by Leyden about twenty years ago are not believed to be concerned in the causation of the paroxysms. As before stated, there is usually, but not always, a certain amount of bronchitis in asthma. This bronchial inflammation doubtless greatly increases the tendency to the disease, and probably in many cases is directly responsible for it by increasing the irritability of the respiratory mucous membrane. The ætiological relations of asthma are not, however, perfectly understood. There is, no doubt, an important hereditary influence in some cases, but the great majority are not referable to this cause. Among the causative factors besides bronchitis may be mentioned enlarged and inflamed bronchial glands, nasal catarrh, amygdalitis, the inhalation of irritants, such as dust, the pollen of certain plants, etc. Reflex disorders of the alimentary tract, uterus, and ovaries are also probably concerned in some instances. The diagnosis of bronchial asthma is easily made (1) by the paroxysmal nature of the attacks, and (2) by the absence of the physical signs of other pulmonary or of cardiac troubles. The differential points between asthma and emphysema will be discussed in speaking of the latter disease.

With reference to the prognosis, we can not speak very hopefully in our present case. In youth the tendency is toward recovery, but in a person of this old lady's age there is a great probability that it will continue during life. The persistence of the disease may possibly lead to the development of other pulmonary troubles, more especially to emphysema. There is always a transitory emphysema during the asthmatic paroxysms. The alveoli become very much distended, and with repeated attacks are liable to lose their elasticity and remain permanently dilated. This leads to an extreme attenuation of the interalveolar walls and finally to rupture, two or more cells becoming merged into one emphysematous bleb. Lobular pneumonia or pulmonary œdema may also result from the frequent congestion of the small bronchi involved in the asthmatic attacks. During the paroxysms the right side of the heart has a much greater amount of work to do than usual, in order to drive the blood through the distended and congested vessels. This may lead to enlargement and dilatation of the right cavities, and eventually to renal disease and dropsy. However, these terminations of asthma are rather the exception than the rule, and, though we should make no promise to cure the disease, we can do much to allay its severity and increase the patient's comfort. The treatment resolves itself

naturally into measures to mitigate the intensity of the paroxysms and to prevent their recurrence. During the seizure the patient intuitively seeks relief by going to an open window and sitting in a bending position, with the elbows on a table or on the knees. This natural instinct should be encouraged by having the clothing about the chest and abdomen loose and free from constrictions. If the weather will permit, all the windows of the apartment should be raised. Any exciting cause which may be discovered should be removed as speedily as possible. I have seen severe asthmatic attacks relieved by a hot rectal injection or an ipecac emetic. The remedial agent I employ most largely for the paroxysms is Hoffmann's anodyne. Thirty drops of this preparation may be given at the outset (to adults), and repeated two or three times at half-hour intervals if required. It acts well in conjunction with strong black coffee given *ad libitum*. These measures will relieve many cases, but they are not always efficient, and we shall not infrequently find it necessary to run the gamut of remedies without finding one that is. A hypodermic injection of eight or ten minims of Magendie's solution of morphine with about one eightieth of a grain of atropine will sometimes abort an attack, although I am aware that so distinguished an authority as Salter declaims against the use of opiates as being rather harmful than of any benefit in the treatment of asthma. In a severe case at the Bellevue chest clinic a few days ago this dose cut short an attack in a few minutes. A combination of Hoffmann's anodyne and the U. S. P. (1870) solution of morphine, constituting the mistura asthmatica of the Bellevue formulary, will often prove efficacious. I have seen good results from the inhalation of a few whiffs of chloroform, but the inhalation of nitrite of amyl as well as the internal administration of nitroglycerin has not been successful in my hands. Various other remedies, including brandy, stramonium, arsenic, eucalyptus, lobelia, musk, valerian, niter paper, etc., have been recommended, but it is beyond our province to attempt a discussion of all these agents. In the case before us, as in the majority of asthmatics, the treatment of the intervals is to be directed to the accompanying bronchitis. This may be treated in accordance with the directions mentioned in our remarks on chronic bronchitis, but here we should not fail to add the iodide of potassium to the cough mixture in doses of five, ten, fifteen, or twenty grains three or four times a day. If we find that the bronchitis is not amenable to treatment, or the attacks are purely neurotic in character, we can hardly hope to cure the disease with medicines. A change of surroundings or climate is then advisable. Generally speaking, persons with asthma are more comfortable in the pure fresh air of mountainous or hilly country districts, but it sometimes happens that persons living in the country escape their asthmatic paroxysms by coming to the city. The climatic part of the treatment is, therefore, in a great degree experimental.

Lecture III.

Chronic Vesicular Emphysema.—Our first patient this morning, gentlemen, is J. L., a 'longshoreman, aged fifty-three. He is a rather stout, strongly-built man, and does not appear to be out of health, yet we shall find that his disease almost destroys his power to earn his living. Several years ago—he does not remember how many—his trouble came on with a great cough. This cough did not leave him entirely, and, after a winter or two, he commenced to suffer from shortness of breath, which came on especially after some unusual exertion, and did not seem to trouble him much as long as he was quiet. The dyspnœa has continued to increase gradually until now he is unable to walk half a dozen blocks without feeling it. As his work is very heavy, he finds this symptom a great hindrance to him. If you examine his skin closely, especially about his chest, you will notice that it is traversed by numerous minute blood-vessels, which give it a rather congested appearance. The veins about the neck are also abnormally prominent. The breathing movements, too, are not natural. There seems to be considerable motion about the chest and neck, but it is to a great extent produced by the voluntary muscles of respiration. It is not expansive in character, but almost entirely of the up-and-down variety. A close inspection will show you that the ribs rotate very little, and there is but a slight increase in the size of the intercostal spaces during a deep inspiration. The lower part of the chest has the appearance of being too prominent in front, although there is no decided bulging. When I lay my hand on the chest, I find that palpation confirms inspection so far as the chest movements are concerned, but I am not sure that the vocal fremitus is at all modified. Mensuration we find to be an important method of examination in this case. On a level with the sixth rib in front I find the chest to measure, at the end of a deep inspiration, thirty-nine inches, while at the end of a prolonged expiration it is thirty-seven inches and a half. This shows a variation of only an inch and a half, which is much less than it should be in a person of this man's physique and laborious manual occupation. An expansion of three or four inches would be nearer normal. When I percuss the chest, I find resonance all over the lungs on both sides; but what kind of resonance is it? You will observe that it exists in situations where we find dullness or flatness normally, as over the precordial region, low down over the liver, etc., and you will observe also that the quality differs somewhat from ordinary healthy resonance, having here something of a metallic character. It is a good example of the vesiculo-tympanitic resonance first described by Professor Flint. On auscultation, I find an occasional mucous râle, and I find also a great change in the respiratory rhythm. The expiration is very long, indeed twice as long as inspiration, whereas in health it should be shorter, the proportion being about as ten to eight. In addition, the expiration is very low-pitched, being almost inaudible low down posteriorly. I can make out no appreciable change in the vocal sounds. On examining the heart, I find the signs of an hypertrophied right ventricle.

From this man's history and the physical signs which are present, we make out a very well marked case of vesicular pulmonary emphysema; not one of those exaggerated cases, with a barrel chest, a displaced heart, and œdematous extremities, but still sufficiently developed to leave

no reasonable doubt as to the diagnosis. If we could see his lungs, I feel no doubt that we would find them enlarged and extending beyond their natural limits. We should find numerous air-blebs caused by overdistention and coalescence of the pulmonary alveoli. This condition would be most marked along the free margins and at the apices of the lungs. If we were very careful, we should also see traces of atelectasis or collapse of the air-vesicles in some portions of the lungs. Adjacent to the dilatations there would doubtless be certain pigmentary changes owing to a transudation of coloring matter from the small alveolar blood-vessels These vessels, by the distention of the alveolar walls, become so compressed as to allow the passage of the watery elements only; hence the pigmentary deposits. When this condition continues long, as it doubtless has done here, some of the little vessels become obliterated, and, the pulmonary circulation being thus impeded, a backward pressure is extended through the pulmonary artery upon the right ventricle, which soon yields to dilatation and enlargement. We have already discovered the physical evidences of right ventricular enlargement in this case. The usual lesions of chronic bronchitis are no doubt present here, and there is probably also a hypertrophic thickening of the muscular coats of the bronchial walls. In the diagnosis of the case we can readily exclude phthisis and pleurisy with effusion by the absence of the physical signs of those diseases. Pneumothorax is excluded by its great rarity, by its absolutely tympanitic percussion note, by its (usually) sudden onset, and by the fact of its being almost always unilateral. The case differs from spasmodic asthma, pure and simple, in the fact that the dyspnœa is brought on by exertion and is not paroxysmal. He thinks he has had asthmatic attacks, however, and this does not surprise me, as there is undoubtedly a very close relationship between the two diseases. All asthmatics do not become emphysematous; but you will find, on careful inquiry, that almost every case of pulmonary emphysema begins with or is preceded by spasmodic asthma. As to the exact mode of development of vesicular emphysema, two principal theories, known as the inspiratory and expiratory theory, have held sway. The former was advanced by Laennec, who regarded the presence of bronchitis as an essential factor, and on this point authorities do not differ. This bronchial inflammation leads to a certain amount of exudation in the tubes, causing more or less obstruction to the ingress and egress of air. But expiration, according to Laennec, being less powerful than inspiration, is unable to expel the air drawn in by inspiration, on account of this mucous accumulation. The air-cells in consequence continue to distend until rupture takes place. This explanation of Laennec's was accepted for many years, but is rejected by a majority of modern authorities. According to the observations of Hutchinson, Gairdner, Mendelssohn, and Traube, Laennec was mistaken in his view that inspiration was more powerful than expiration. They have shown that more air was expelled through the tubes involved in the mucous obstruction than was admitted by inspiration. The conformation of the tubes, according to Gairdner, also facilitates the egress while retarding the ingress of air. This consists in the fact that the tubes are smaller as they approach the air-cells, and, of course, larger as they go out. On this account the exudation may act in the nature of a ball-valve, being easily displaced by expiration in the direction of the larger diameter and allowing free exit, but at once closing the tube on inspiration and effectually cutting off the entrance of air. In this way the small amount of air remaining in the air-cells becomes so rarefied that collapse of their walls inevitably ensues. Neighboring air-vesicles receive too much air in consequence, and a vicarious or supplementary emphysema is thus established.

The prognosis in the present case, as in most cases of pulmonary emphysema, is not favorable. There is no considerable danger to life from the affection, but, on the other hand, there is no probability that the patient will ever be entirely well again. The cells which are only dilated may be restored, but the ruptured ones do not admit of reparation. Emphysema increases the danger from intercurrent diseases. It also causes dilatation and hypertrophy of the right side of the heart, which increases the danger. It may even threaten life from the liability of bronchorrhœa, with profuse muco-purulent expectoration occurring and filling the tubes, and thus bring about death from asphyxia. Some authors have taught that the presence of emphysema affords more or less immunity from pneumonia, pulmonary œdema, and consumption. There may be a grain of truth in this, as emphysema diminishes the amount of blood in the lungs—a condition which, as we know, is not conducive to the development of these troubles.

The first indication in the treatment of pulmonary emphysema consists in the employment of measures to prevent the extension of the disease and so far as possible to restore the pulmonary structure to a condition of health. This indication is best carried out by means of nourishing food, fresh air, careful habits, avoidance of strains, etc., and the administration of tonics, more especially some of the preparations of strychnine. One of the most valuable of these is an elixir of the phosphate of iron, quinine, and strychnine, a teaspoonful of which represents: of the phosphate of strychnine, one sixtieth to one one-hundredth of a grain; phosphate of iron, two grains; and phosphate of quinine, one grain. This dose should be taken three times a day before meals. If it fails to agree, as is not often the case, recourse must be had to other preparations. I do not believe strychnine to possess any peculiar value in restoring the diseased lung tissue, and prescribe it only for its tonic effects. Certain mechanical means, to which we can only allude in the briefest possible manner this morning, have been devised to facilitate resolution of the involved air-vesicles. They mostly involve the principle of pneumatic aspiration, the patient inhaling condensed air and exhaling into rarefied air. The idea involved is that the inhalation of condensed air retards the respiration, allowing more oxygen to be consumed, and thus causes a more complete tissue metamorphosis; while exhaling into rarefied air facilitates the withdrawal of the abnormal amount of residual air in the distended alveoli. The most satisfactory apparatus with which I am acquainted is that of Waldenburg, as modified by Tobold and manufactured by

of oxygen inspired, but in the variation from the normal amount of carbonic acid in the blood circulating through the respiratory center of each animal, is to be concluded from the researches especially of Gad and M. Rosenthal (7), Miescher (14), Kempner (15), and others.

The delicate reaction of the respiratory center to a change in the constitution of the blood in this experiment, together with the many current facts showing the influence of nervous impressions reflected upon this center, convey an idea of its importance for the regulation of the respiration under various circumstances of the individual.

Two observations of Gad (1) and Sig. Mayer (16) show, furthermore, the change in the excitability of the respiratory center which is effected by considerable changes in the blood-supply. The former observer, on diminishing the flow of blood to the brain for a time and then restoring the current to its previous amount, observed a stoppage of respiration. The latter noted the same on occasioning a pause in the heart's action.

We have in these experiments a demonstration of the two ground factors in the above-mentioned regulation—namely, the excitability of the spino-bulbar respiratory center, and the constantly present excitant of the same, as well as a proof of the variability of each of these factors whereby this regulation becomes effected.

In respect of the experiments of Head, cited by Dr. Meltzer in support of his theory, it is to be noted that the former, without expressly stating what he does regard as the causation of the results obtained by him, refers to the after-effect upon the action of the diaphragm of his prolonged insufflations of the lungs, in the following words, the here Italicized portions of which alone concern us in this connection:

If the lungs are inflated, the expiratory pause produced by the inflation is finally broken by an inspiratory contraction, although the lungs are still dilated. This contraction is strong, of comparatively short duration, and traces a curve with an extremely sharp crest. But if the lungs are allowed to return to the normal volume just before this interrupting inspiration would normally have made its appearance, the breathing undergoes a very different modification.

At the moment of collapse the inspiratory muscles contract strongly, and produce a strong, flat-topped curve. This contraction is of about the same strength as the interrupting inspiration, but exceeds it greatly in duration. Thus sudden return of the lungs to the normal volume after an inflation of considerable duration produces a strong and long inspiratory contraction. *It might be objected that both the interrupting inspiration and the strong inspiratory effect which follows collapse after an inflation were due to the dyspnœa which must necessarily result during such a long pause in the breathing. However, I think that this explanation will scarcely suffice to explain either phenomenon; for, provided the inflations are of the same strength, the pause is broken at almost exactly the same moment, whether oxygen, air, or hydrogen be used to inflate the lungs.*

It is true that the strength of the interrupting contraction is generally greatest when the lungs have been inflated with hydrogen, but the time of its appearance is the same with all three gases under otherwise similar conditions.

Again, the fact that the animal is breathing oxygen during and after the inflation does not diminish the strength of the inspiratory contraction, which is produced by the sudden return of the lungs to their normal volume after the inflation. *Indeed, it is rather favorable than otherwise to its appearance, for, if the animal is dyspnœic, this inspiratory contraction is of much shorter duration and is much more difficult to produce than when the lungs have been inflated with air or oxygen.*

It will be noticed in the above that the author, without leaving the question an open one, does not distinctly hold these inspirations, during or after prolonged insufflations of the lungs, to be due to central (direct) or to peripheral (reflex) incitation; namely, to vitiated blood in the medulla, or to excitation of the vagus in the lungs; but it is evident that the latter is his view.

This conclusion does not seem to me to follow, however, from the simple circumstance stated, that the interrupting inspiratory effort was stronger on the use of hydrogen than of air or oxygen.

Exception may also be taken here to the author's use of the word dyspnœa, whereby he wrests it from its universal clear and symptomatic meaning of increased respiratory effort with want of air, and devotes it to a condition of the respiratory center, due to vitiation of blood, for the reason, namely, that neither of these definitions includes the other; for we may have, on the one hand, as already detailed, a peripherally arising dyspnœa, and on the other, as in the experiments of Gad and of Sig. Mayer, already cited, a vitiation of the blood with diminished rather than increased breathing; or, as in the author's case, a diminished respiratory effort with increasing vitiation of the blood, until finally the inhibition of the respiration is broken through by the increased excitation of the center; or, again, a stoppage of the breathing after a dyspnœic patient draws the first long breath or two upon a tracheotomy, or the same when, after a severe hæmorrhage, a transfusion is quickly made; and yet in all these cases the center contain vitiated blood and tissue fluid, the condition of which has only begun to become normal.

The difficulties, moreover, to which such a conception of dyspnœa are apt to lead is illustrated in the last sentence of the quotation, in which the animal is spoken of as "dyspnœic," when in reality it is apnœic (17).

That the above-mentioned experiment, as given to us, is, furthermore, of altogether too complicated a nature to be more than food for controversy, or better, perhaps, for further investigation, is indicated by the following considerations, as well as by the description itself:

1. It has been shown, especially by the above-cited experiments of Gad and M. Rosenthal, which covered the use of both gases concerned, that dyspnœa unmistakably appears upon a slight increase of the carbonic acid in the inspired air, while a much greater corresponding decrease of oxygen in an atmosphere breathed is requisite for a similar effect; in fact, they consider that in respiration from a limited air space the dyspnœa is in reality occasioned by the carbonic acid.

2. In the above-cited experiments of Head, the conditions for the diffusion of carbonic acid from the blood into the pulmonary alveoli were apparently the same in all three cases.

3. By reason of the quietude of the animal, which, in

the first place, narcotized, in the second made no respiratory effort, the general consumption of oxygen was undoubtedly small; the vitiation of the blood in general was, therefore, reduced to a minimum from the beginning of the experiment on.

4. As the respiratory center had ceased its respiratory activity, we may assume both its call for oxygen and the vitiation of the blood and tissue fluid within it to have been abnormal—to have been abnormally small.

5. In that the insufflations with hydrogen, commencing during normal respiration, were superimposed upon the residual plus the reserve atmospheric air then in the chest, there was merely less oxygen available therein than when air or oxygen was injected.

6. By their considerable duration (some twenty seconds), and the continually lessening hæmatosis, especially in the case of the hydrogen insufflations, the excitability of the respiratory center would by this of itself be reduced—would not, therefore, respond so quickly or so well (1, 16). That this was the case is to be seen from the last sentence of the quotation, which seems to contradict the previous statement concerning the effect of hydrogen.

7. Where less oxygen is furnished to the organism, less carbonic acid is formed (15).

8. The data given are insufficient for estimating the two variable factors at the center—namely, its excitability, and the amount of excitant offered to it.

As indicated at the beginning of this paper, an inhibitory function of the pulmonary vagus in ordinary respiration has been established and without recourse to excitation of the nerve stem—namely, the power of cutting off inspiration and inducing expiration, which was maintained in the first part of the theory of Hering and Breuer.

This fact was rendered probable by the experiments of these observers (2), who noted the effect on the respiratory efforts of pulmonary insufflations in the intact animal and the absence of such effect after the vagus was cut. The conclusive proof of the same was brought by Gad (1), who, by using chloral instead of opium as a narcotic, by a means of precisely and continuously registering the changes in the volume of the lungs with inspiration and expiration (18), but chiefly by the employment of a new and trustworthy method of suddenly interrupting the nervous impulses coursing through the vagus without exciting the nerve thereby—namely, by locally freezing it—was enabled to observe, so soon as this latter was done, that the inspirations were deepened and their frequency reduced, just as is found some time after cutting the vagi, and also that the respiration was carried on with a much greater distention of the chest, while a new pause, relative or absolute, appeared at the end of inspiration, and the normal one at the end of expiration in ordinary quiet respiration disappeared, so that the tracing of the latter appeared inversed and magnified from the moment on when both nerves were frozen through, although the animal often breathed less air thereafter than before.

From this alteration of the type of respiration it is evident that a restraining, an inhibitory influence has been removed; for, as above said, not only were the individual inspirations now deeper, but the inspiratory muscles continued each time in a state of contraction after the inflow of air had ceased, while the expirations were cut short by a new inspiration, so that altogether the mean expansion of the chest remained by a considerable amount above its former level.

We are also furnished, however, by the above experiment with the presumption of the sufficiency of the direct action of the respiratory center in inciting inspiration, for the respiratory activity upon eliminating the influence of the vagi, instead of decreasing, has markedly increased. We find, moreover, in the following experiments of Flint (19), to which we would call especial attention by reason of their obvious incompatibility with the theory of Dr. Meltzer, a further evidence of the sufficiency of the action of the respiratory center for the incitation of ordinary respiration. This observer noted in an animal abundantly and regularly supplied with air by a bellows, and which in consequence thereof had ceased respiratory effort, that the latter would begin upon letting arterial blood, and that the same would occur whether the vagi were intact or cut. The conclusion of the author therefrom—that the incitation to inspiration did not flow from the lungs—was the first emancipation from the confusion that seems to have been stamped upon the subject by the various memoirs of Marshall Hall (20). The complement to this was furnished by Rosenthal (11*a*), who showed, by cutting the various cerebral and sensory paths to the medulla oblongata, that respiration was not a reflex act.

Hermann and Escher (21), by occluding the veins leading from the brain and cervical cord, showed that it was merely lack of circulation and not the emptiness of the blood-vessels by which, in Rosenthal's researches on this point, the dyspnœa was caused, and that therefore the conclusion of the latter—that occlusion of the cerebral arteries acted by disturbing the tissue changes in the center—was justified.

As pointed out by Gad, the pause following normal quiet expiration indicates that the inhibitory influence from the vagus, which cuts off the inspiration, overlasts the latter. The existence of this pause at the end of expiration and the absence of such at the end of normal inspiration are adduced by him, in addition to the presumable sufficiency of the central incitation to inspiration, against the second part of the theory of Hering and Breuer, according to which the inspiration is incited by reflex from the diminishing lung, just as expiration is induced by inhibitory reflex from the expanding lung.

As this view still remains undemonstrated, notwithstanding extended researches directed to the same (4), we may regard the causation of the respiratory rhythm in the following manner, substantially as formulated by Gad, who divides it into three factors, namely:

1. To incite inspiration: The constant presence in the respiratory center of an excitant, probably carbonic acid.

2. To occasion expiration: The lowering of the excitability of the center below the point of response to the amount of excitant present through mechanical excitation of the vagus in the lung in inspiration.

of oxygen inspired, but in the variation from the normal amount of carbonic acid in the blood circulating through the respiratory center of each animal, is to be concluded from the researches especially of Gad and M. Rosenthal (7), Miescher (14), Kempner (15), and others.

The delicate reaction of the respiratory center to a change in the constitution of the blood in this experiment, together with the many current facts showing the influence of nervous impressions reflected upon this center, convey an idea of its importance for the regulation of the respiration under various circumstances of the individual.

Two observations of Gad (1) and Sig. Mayer (16) show, furthermore, the change in the excitability of the respiratory center which is effected by considerable changes in the blood-supply. The former observer, on diminishing the flow of blood to the brain for a time and then restoring the current to its previous amount, observed a stoppage of respiration. The latter noted the same on occasioning a pause in the heart's action.

We have in these experiments a demonstration of the two ground factors in the above-mentioned regulation—namely, the excitability of the spino-bulbar respiratory center, and the constantly present excitant of the same, as well as a proof of the variability of each of these factors whereby this regulation becomes effected.

In respect of the experiments of Head, cited by Dr. Meltzer in support of his theory, it is to be noted that the former, without expressly stating what he does regard as the causation of the results obtained by him, refers to the after-effect upon the action of the diaphragm of his prolonged insufflations of the lungs, in the following words, the here Italicized portions of which alone concern us in this connection:

If the lungs are inflated, the expiratory pause produced by the inflation is finally broken by an inspiratory contraction, although the lungs are still dilated. This contraction is strong, of comparatively short duration, and traces a curve with an extremely sharp crest. But if the lungs are allowed to return to the normal volume just before this interrupting inspiration would normally have made its appearance, the breathing undergoes a very different modification.

At the moment of collapse the inspiratory muscles contract strongly, and produce a strong, flat-topped curve. This contraction is of about the same strength as the interrupting inspiration, but exceeds it greatly in duration. Thus sudden return of the lungs to the normal volume after an inflation of considerable duration produces a strong and long inspiratory contraction. *It might be objected that both the interrupting inspiration and the strong inspiratory effect which follows collapse after an inflation were due to the dyspnœa which must necessarily result during such a long pause in the breathing. However, I think that this explanation will scarcely suffice to explain either phenomenon; for, provided the inflations are of the same strength, the pause is broken at almost exactly the same moment, whether oxygen, air, or hydrogen be used to inflate the lungs.*

It is true that the strength of the interrupting contraction is generally greatest when the lungs have been inflated with hydrogen, but the time of its appearance is the same with all three gases under otherwise similar conditions.

Again, the fact that the animal is breathing oxygen during and after the inflation does not diminish the strength of the inspiratory contraction, which is produced by the sudden return of the lungs to their normal volume after the inflation. *Indeed, it is rather favorable than otherwise to its appearance, for, if the animal is dyspnœic, this inspiratory contraction is of much shorter duration and is much more difficult to produce than when the lungs have been inflated with air or oxygen.*

It will be noticed in the above that the author, without leaving the question an open one, does not distinctly hold these inspirations, during or after prolonged insufflations of the lungs, to be due to central (direct) or to peripheral (reflex) incitation; namely, to vitiated blood in the medulla, or to excitation of the vagus in the lungs; but it is evident that the latter is his view.

This conclusion does not seem to me to follow, however, from the simple circumstance stated, that the interrupting inspiratory effort was stronger on the use of hydrogen than of air or oxygen.

Exception may also be taken here to the author's use of the word dyspnœa, whereby he wrests it from its universal clear and symptomatic meaning of increased respiratory effort with want of air, and devotes it to a condition of the respiratory center, due to vitiation of blood, for the reason, namely, that neither of these definitions includes the other; for we may have, on the one hand, as already detailed, a peripherally arising dyspnœa, and on the other, as in the experiments of Gad and of Sig. Mayer, already cited, a vitiation of the blood with diminished rather than increased breathing; or, as in the author's case, a diminished respiratory effort with increasing vitiation of the blood, until finally the inhibition of the respiration is broken through by the increased excitation of the center; or, again, a stoppage of the breathing after a dyspnœic patient draws the first long breath or two upon a tracheotomy, or the same when, after a severe hæmorrhage, a transfusion is quickly made; and yet in all these cases the center contain vitiated blood and tissue fluid, the condition of which has only begun to become normal.

The difficulties, moreover, to which such a conception of dyspnœa are apt to lead is illustrated in the last sentence of the quotation, in which the animal is spoken of as "dyspnœic," when in reality it is apnœic (17).

That the above-mentioned experiment, as given to us, is, furthermore, of altogether too complicated a nature to be more than food for controversy, or better, perhaps, for further investigation, is indicated by the following considerations, as well as by the description itself:

1. It has been shown, especially by the above-cited experiments of Gad and M. Rosenthal, which covered the use of both gases concerned, that dyspnœa unmistakably appears upon a slight increase of the carbonic acid in the inspired air, while a much greater corresponding decrease of oxygen in an atmosphere breathed is requisite for a similar effect; in fact, they consider that in respiration from a limited air space the dyspnœa is in reality occasioned by the carbonic acid.

2. In the above-cited experiments of Head, the conditions for the diffusion of carbonic acid from the blood into the pulmonary alveoli were apparently the same in all three cases.

3. By reason of the quietude of the animal, which, in

the first place, narcotized, in the second made no respiratory effort, the general consumption of oxygen was undoubtedly small; the vitiation of the blood in general was, therefore, reduced to a minimum from the beginning of the experiment on.

4. As the respiratory center had ceased its respiratory activity, we may assume both its call for oxygen and the vitiation of the blood and tissue fluid within it to have been abnormal—to have been abnormally small.

5. In that the insufflations with hydrogen, commencing during normal respiration, were superimposed upon the residual plus the reserve atmospheric air then in the chest, there was merely less oxygen available therein than when air or oxygen was injected.

6. By their considerable duration (some twenty seconds), and the continually lessening hæmatosis, especially in the case of the hydrogen insufflations, the excitability of the respiratory center would by this of itself be reduced—would not, therefore, respond so quickly or so well (1, 16). That this was the case is to be seen from the last sentence of the quotation, which seems to contradict the previous statement concerning the effect of hydrogen.

7. Where less oxygen is furnished to the organism, less carbonic acid is formed (15).

8. The data given are insufficient for estimating the two variable factors at the center—namely, its excitability, and the amount of excitant offered to it.

As indicated at the beginning of this paper, an inhibitory function of the pulmonary vagus in ordinary respiration has been established and without recourse to excitation of the nerve stem—namely, the power of cutting off inspiration and inducing expiration, which was maintained in the first part of the theory of Hering and Breuer.

This fact was rendered probable by the experiments of these observers (2), who noted the effect on the respiratory efforts of pulmonary insufflations in the intact animal and the absence of such effect after the vagus was cut. The conclusive proof of the same was brought by Gad (1), who, by using chloral instead of opium as a narcotic, by a means of precisely and continuously registering the changes in the volume of the lungs with inspiration and expiration (18), but chiefly by the employment of a new and trustworthy method of suddenly interrupting the nervous impulses coursing through the vagus without exciting the nerve thereby—namely, by locally freezing it—was enabled to observe, so soon as this latter was done, that the inspirations were deepened and their frequency reduced, just as is found some time after cutting the vagi, and also that the respiration was carried on with a much greater distention of the chest, while a new pause, relative or absolute, appeared at the end of inspiration, and the normal one at the end of expiration in ordinary quiet respiration disappeared, so that the tracing of the latter appeared inversed and magnified from the moment on when both nerves were frozen through, although the animal often breathed less air thereafter than before.

From this alteration of the type of respiration it is evident that a restraining, an inhibitory influence has been removed; for, as above said, not only were the individual inspirations now deeper, but the inspiratory muscles continued each time in a state of contraction after the inflow of air had ceased, while the expirations were cut short by a new inspiration, so that altogether the mean expansion of the chest remained by a considerable amount above its former level.

We are also furnished, however, by the above experiment with the presumption of the sufficiency of the direct action of the respiratory center in inciting inspiration, for the respiratory activity upon eliminating the influence of the vagi, instead of decreasing, has markedly increased. We find, moreover, in the following experiments of Flint (19), to which we would call especial attention by reason of their obvious incompatibility with the theory of Dr. Meltzer, a further evidence of the sufficiency of the action of the respiratory center for the incitation of ordinary respiration. This observer noted in an animal abundantly and regularly supplied with air by a bellows, and which in consequence thereof had ceased respiratory effort, that the latter would begin upon letting arterial blood, and that the same would occur whether the vagi were intact or cut. The conclusion of the author therefrom—that the incitation to inspiration did not flow from the lungs—was the first emancipation from the confusion that seems to have been stamped upon the subject by the various memoirs of Marshall Hall (20). The complement to this was furnished by Rosenthal (11*a*), who showed, by cutting the various cerebral and sensory paths to the medulla oblongata, that respiration was not a reflex act.

Hermann and Escher (21), by occluding the veins leading from the brain and cervical cord, showed that it was merely lack of circulation and not the emptiness of the blood-vessels by which, in Rosenthal's researches on this point, the dyspnœa was caused, and that therefore the conclusion of the latter—that occlusion of the cerebral arteries acted by disturbing the tissue changes in the center—was justified.

As pointed out by Gad, the pause following normal quiet expiration indicates that the inhibitory influence from the vagus, which cuts off the inspiration, overlasts the latter. The existence of this pause at the end of expiration and the absence of such at the end of normal inspiration are adduced by him, in addition to the presumable sufficiency of the central incitation to inspiration, against the second part of the theory of Hering and Breuer, according to which the inspiration is incited by reflex from the diminishing lung, just as expiration is induced by inhibitory reflex from the expanding lung.

As this view still remains undemonstrated, notwithstanding extended researches directed to the same (4), we may regard the causation of the respiratory rhythm in the following manner, substantially as formulated by Gad, who divides it into three factors, namely:

1. To incite inspiration: The constant presence in the respiratory center of an excitant, probably carbonic acid.

2. To occasion expiration: The lowering of the excitability of the center below the point of response to the amount of excitant present through mechanical excitation of the vagus in the lung in inspiration.

3. For the continuance of expiration: A persistence of this effect until the excitability of the center has again become sufficiently great to determine reaction to the excitant.

Upon this basis a regulation of the respiration—namely, of the depth and frequency of the respiratory efforts and of the mean distention of the chest, according to the position, condition, and activity of the individual—would depend (1) upon the constituency of the blood furnished to the respiratory center, and (2) upon the nervous impulses of various kinds which, reflected upon the respiratory center, raise or diminish its excitability, the latter acting to supplement the former, just as at birth a cold shock assists the stoppage of the placental circulation in occasioning the first respiratory efforts.

With reference to the constant influence of the vagus upon respiration, which we have already noted in the researches of Gad on the normally breathing animal, the following experiment by Hering and Breuer (2), which demonstrated the presence of such an influence under the conditions specified and showed it to be independent of the motions of the lungs, concerns us respecting the theory of Dr. Meltzer at this point. Upon sending a constant, even current of air through the thereby distended and multiply-punctured lungs, the rhythmic respiratory efforts continue, and they at once diminish in frequency upon cutting the vagi, just as in the normally breathing animal.

Recently it has been found by Loewy (22) that, by rendering one lung airless, impulses cease to flow therefrom to the respiratory center through the vagus, which was shown by cutting the vagus of the other lung, when the respiration changes, just as after section of both vagi in the normal animal, while section of the nerve on the side of the atelectatic lung causes no change in the respiration; and it has been confirmed by inflating the airless lung, when, if its vagus be intact, the former frequency, and we may allow ourselves to believe also the former type of respiration, is restored.

These experiments, as well as the simple pulmonary insufflations of Hering and Breuer and of Head, have been considered to show that it is the expansion of the lung that excites the fibers inhibitory of inspiration in the vagus, and Dr. Meltzer has founded his theory of respiratory rhythm, as before stated, on this idea.

Without going further into the question in this place, I wish, however, to call attention to the fact that this is only an inference; for in the experiments of the above-named observers there was, besides expansion, also pressure present, and, in fact, considerable pressure, the influence of which, if it have an influence, was not excluded or considered by them.

The researches of Loewy, in the absence of such exclusion, simply show that the constant normal inhibitory influence of the vagus on the respiration may be due to the state of expansion of the lungs, or to their intermittent active expansions, or to the intermittent pressure or rise of pressure in the alveoli, or to some two or all of these.

But another supposition in this theory deserves attention, in that it could have been readily avoided by leaving the question an open one—namely, the assumption of two kinds of pulmonary fibers in the vagus for ordinary respiration; the one for inspiration, the other for inhibition of the same; for it is possible that, by reason of the nature of their connections with the central ganglia, or of their endings in the lungs, one set of fibers suffices for all functional purposes, so that one degree or kind of excitation effects ordinary incitations or inhibitions; other degrees or kinds of excitation, extraordinary incitations or inhibitions. This is an alternative, mentioned indeed by Hering and Breuer in connection with their own experiments, and were still more worthy of regard in building upon the effects of artificial excitation of the nerve stem.

In conclusion, it remains only to note that the communication of Dr. Meltzer is restricted to his explanation of the respiratory rhythm, and does not concern itself with the regulation of respiration; indeed, the question that very naturally suggests itself—namely, what self-regulation of the respiration can, under any normal circumstances, be exerted alone by an expanding lung, which by one and the same process excites both inhibiters and exciters of the respiration—is not even alluded to.

THE EXTRACTION OF LENSES DISLOCATED INTO THE VITREOUS.*

By CHARLES STEDMAN BULL, M. D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF THE CITY OF NEW YORK; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; CONSULTING OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL AND TO ST. MARY'S HOSPITAL FOR CHILDREN.

Since the publication of the recent papers by Dr. Agnew, Dr. Webster, Dr. Pomeroy, and Dr. Knapp upon the subject of the extraction of lenses dislocated into the vitreous, the writer has collected a number of cases of dislocation of the lens into the vitreous, due to traumatism, which have been operated upon by himself during a period of several years, and now presents the histories of the following thirteen cases, with some remarks upon the method of operating, for the consideration of the society. The interest excited by a description of the method devised by Dr. Agnew, with an instrument—the bident—invented by himself, has not sufficed to conceal from the mind of the writer the real value of the objections raised against the use of this instrument. None of the cases described in detail in this paper were operated upon with the bident, and the writer has had no personal experience with the instrument. No very great difficulty has ever been experienced in attempting to remove lenses dislocated into the vitreous by the methods hitherto in general use, and in none of the cases here reported have any bad results followed. The extraction of a lens from the vitreous is a more or less difficult operation, and any case may very well differ from all others in some minor points. The more serious the traumatism has been, and the greater the resulting disorganization of the eye, the more difficult will be the operation for the removal of such a dislocated lens, and the more serious the possible accidents during the operation.

The writer's experience is in accord with that of Dr. Knapp, who believes it possible, "by external manipulation, to extract lenses dislocated and swimming in the vitreous without accident and with preservation of the natural pupil." Not only is this true with regard to lenses entirely dislocated and floating freely in the vitreous, but the same remark may be applied to partially dislocated lenses, and to lenses floating in the vitreous, but attached at one point to the ciliary processes. The writer believes it possible in many cases, perhaps in the great majority, to extract the lens by external pressure, and to confine the use of instruments to assisting in the removal of the lens after it has presented in the wound, or at least in the field of the pupil. Of course, in each case the possible difficulties are an unknown quantity, and the blunt hook, the delicate wire spoon, or the broad silver spoon should be ready at hand to use in case of necessity.

The manipulation which the writer has found useful in this operation may be described as follows: The eyelids are held open by the ordinary wire speculum, and the corneal section is made upward with the narrow knife, the ends of the incision being in the limbus, and the apex in clear cornea, just below the limbus. The speculum is then removed, and the upper lid is lifted up and away from the eyeball by the finger of an assistant, or, better, by a wire elevator held by an assistant. Pressure is then made upon the lower part of the eyeball with the thumb or finger of the operator, by pressing the lower lid against the eye directly backward. Almost immediately the lens will be seen to rise and appear in the field of the pupil, and, in not a few instances, comes partially through the pupil and engages in the wound. Sometimes the assistance of a blunt hook or the wire spoon becomes necessary to complete the removal of the lens at this stage of the operation. If continued pressure backward fails to push the lens through the pupil, or causes a prolapse of the vitreous, it should be discontinued, and the lens removed at once by hook or spoon. It is surprising to see how often a dislocated lens is removed by this simple pressure backward, without the introduction of any instrument into the eye. If a criticism may be passed upon the use of the bident by one who has never used it, it would seem to the writer that the objections to its use raised by Dr. Knapp are just. The sclerotic and ciliary regions are pierced in four places by the teeth of the bident, and after the lens is extracted, both aqueous and vitreous chambers being open, this instrument must then be withdrawn. Another objection to its use is that it decidedly complicates the operation by adding one more to the number of instruments necessary for it, and by the introduction of this instrument inside the eye, where it must remain until the lens has been extracted.

Case I.—Patrick McD., aged seventy-five, June 3, 1878. Has had gradually failing vision in both eyes for several years. One month ago he received a severe blow on the left eye and lost the sight in this eye at once, and since then has had only perception of light. There have been occasional attacks of pain.

R. E., $\frac{20}{70}$; partial opacity of the lens; sluggish iris; senile degenerative chorioiditis.

L. E., V. = perception of light; pupil irregularly dilated and immovable; iris discolored and fluttering; lens dislocated downward into the vitreous, entirely opaque and floating free. T. + 1.

It was determined to attempt the removal of the dislocated

* Read before the American Ophthalmological Society, July 16, 1890.

lens. This was before the days of cocaine, and the patient declined to take ether. The patient was placed on his back in bed, and a wire speculum was introduced to hold the lids open. The eye and *cul-de-sac* were carefully washed with a warm saturated solution of boric acid. The eyeball was then steadied by fixation forceps, and an upper corneal section made with a narrow Graefe knife, the ends of the section being in the limbus and the apex in clear cornea. The speculum was then removed, in the course of which the lens presented in the pupil, which was a fortunate accident. A blunt hook was then carefully introduced through the corneal wound, hugging the upper segment of the iris, and passed slowly behind the upper presenting margin of the lens. By a sudden delicate twist the blunt point of the hook penetrated the lens capsule, and the lens was at once lifted through the pupil and corneal wound and removed from the eye, followed by a small amount of vitreous. The cornea at once collapsed, and, as a consequence, the wound gaped. Atropine was instilled and a bandage carefully applied. Much of the success of this operation was due to the extraordinary self-control of the patient, who lay perfectly still, with an immovable eye, until all was over. The eye was dressed daily, but the wound remained open for a long time, and did not entirely close for nearly a month. The iris, which had partially prolapsed at the time of the passage of the lens through the wound, replaced itself and gave no further trouble. There was no improvement of vision in the left eye, probably owing to the effects of the contusion. This patient subsequently underwent an operation for extraction of cataract in the right eye three years later, and recovered useful vision of $\frac{20}{70}$.

Case II.—Henry H., aged sixty-five, December 16, 1878. Twenty years before, this patient had received a violent blow on the *right* eye, which caused complete dislocation of the lens into the vitreous. The blow destroyed the sight at once, and nothing more than perception of light has ever been regained. Attacks of intra-ocular irritation have appeared at irregular intervals, but subsided after a few days of treatment. Two weeks ago an unusually severe attack began, and has continued ever since, with much pain.

R. E., perception of light. Signs of ciliary irritation, with injection of the eye and photophobia. Large, opaque lens floating in the vitreous.

L. E., $\frac{10}{200}$; cataract; field and projection normal.

This patient was etherized, a speculum was introduced, and the eye and *cul-de-sac* were carefully irrigated with a saturated solution of boric acid. The eye was then held by fixation forceps and an upward corneal section made with a narrow knife, entirely in the limbus. The speculum was then removed and an attempt made by pressure on the eyeball through the lower lid to bring the lens into the pupil. This partially succeeded, but vitreous presented in the wound before the lens. A wire spoon was then introduced through the wound and through the pupil into the vitreous behind the partially presenting lens, and at the first attempt the lens was extracted intact in its capsule. Very little vitreous was lost in the operation. The prolapsed iris was stroked into place in the anterior chamber with a spatula, a drop of eserine was introduced, and the eye was carefully bandaged. This patient was operated upon while lying on his back in bed. The eye made an excellent recovery, and the signs of ciliary irritation soon subsided.

Case III.—Jane K., aged twenty-three, October 6, 1880. Patient has had defective vision from birth, with nystagmus and great intolerance of light. Repeated attacks of inflammation in both eyes. For the past two months the right eye has been extremely painful and continually inflamed.

R. E., $\frac{1}{200}$. Hazy cornea, with numerous depressions from old ulcers. Congenital aniridia. Lens dislocated downward and inward into the vitreous, but still attached by two bands to the ciliary processes downward and inward, the remains of the suspensory ligament. Lens opaque.

L. E., $\frac{5}{200}$; congenital aniridia; opacities in lens and capsule; no dislocation of lens. Owing to the dangerously inflamed condition of the right eye, the patient was advised to have an enucleation done, but this she refused, and it was then decided to attempt the removal of the lens. The patient was etherized and an upward corneal section was made, the ends being in the limbus and the apex in clear cornea. Much to my surprise, the lens presented at once in the wound, accompanied by a little vitreous, and was readily removed by the wire spoon, with a slight loss of vitreous. The eye and lids were then carefully and gently irrigated with a solution of mercuric bichloride (1 to 5,000) and an antiseptic bandage was applied. This bandage was left undisturbed for three days and was then removed. The lids looked well and there was no discharge of any kind, so the eye was not opened, and the bandage was reapplied and left on for forty-eight hours longer. At the end of this period it was removed, the eye was examined, and the corneal wound was found entirely closed. There was still considerable ciliary injection and irritation, which was treated by atropine and dark glasses and soon subsided. At no time was there any irritation of the fellow eye.

Case IV.—James B., aged sixty-eight. January 28, 1884. Patient has had failing vision in both eyes for some years. Three months before he had received a violent blow on the right eye from a potato, which for the time completely abolished the vision in this eye. After about a week he began to regain the sight, and it has steadily improved since.

R. E., $\frac{1}{200}$, with sph. + D. 12 = $\frac{20}{40}$; widely dilated pupil; lens opaque and floating freely at the bottom of the vitreous; tension + 1.

L. E., $\frac{20}{200}$; cataract.

On February 13th it was decided to attempt the removal of the lens, which remained in the vitreous and could not be induced to fall into the anterior chamber by any position or manœuvre. The patient refused to be anæsthetized, and the operation was performed while he was seated in a chair. The eyeball was opened by a corneal section upward, the apex in clear cornea, and made with a narrow knife. Pressure was then made upon the lower portion of the eyeball with the thumb and index finger alternately through the lower lid directly backward. This caused a lifting upward and forward of the lens, and at the same time caused a slight gaping of the lips of the wound. As this pressure was continued its direction was changed from backward to backward and upward, and as the lens rose and came forward through the pupil, a blunt hook was introduced through the lips of the wound, engaged in the lens, and the latter was lifted out in its capsule without the slightest difficulty. It was followed by some fluid vitreous. The cornea collapsed, but there was no pain complained of by the patient. The usual antiseptic dressings and bandage were applied and remained unchanged for two days. The case did well, there being no adverse symptoms, but the wound healed very slowly, and it was nearly a month before the anterior chamber was established. The ultimate vision in this eye was $\frac{20}{30}$, with sph. + D. 12.

Case V.—Margaret W., aged twenty-two, May 5, 1884. Patient was struck a violent blow with a fist on the left eye six days before, and vision was lost at once. Since then there has been at times severe pain.

R. E., $\frac{20}{20}$.

L. E., perception of light; small amount of blood in anterior chamber; iridodonesis; traumatic iridochorioiditis; lens dis-

located downward and backward into the vitreous; blood in the vitreous; tension + 2.

On May 28th all the blood was gone from the anterior chamber, and most of the signs of acute inflammation had subsided under the influence of cold applications and atropine. But the tension remained above normal and there was at times considerable pain, and the removal of the lens was deemed advisable. The patient was operated upon on her back in bed, the incision being the usual corneal section upward made with the narrow knife, the apex being in clear cornea. A small bead of vitreous presented in the wound on the withdrawal of the knife, and the speculum was removed at once and the lids closed. After a lapse of five minutes the lids were opened and the upper lid raised by a wire elevator. Gentle pressure directly backward was then made on the lower portion of the eyeball through the lower lid, and this soon brought the lens into the field of the pupil; but any attempt to force it through the pupil toward the wound increased the prolapse of the vitreous. The elevator was then given to an assistant to hold, and a wire spoon was introduced through the wound, then through the pupil and behind the presenting upper margin of the lens, and the latter was then easily removed without any further loss of vitreous. The eyeball and *cul-de-sac* were gently irrigated, and the lids closed under the usual antiseptic dressings. The case did extremely well, no unusual reaction of any kind occurred, and the patient was discharged at the end of the third week with a perfectly quiet, unirritated eye. The vision, however, was not improved.

Case VI.—Moses G., aged forty-five, June 22, 1885. Patient has always been very myopic. He lost the sight in the left eye sixteen years before by a blow from a stick, and the eye was inflamed and painful for several months after the injury. Since then there have been repeated attacks of inflammation in the left eye, the present one having begun one week ago, and the sight of the fellow eye has steadily failed.

R. E., fingers at six feet; myopia; cataract.

L. E., perception of light. Lens opaque, dislocated downward and backward completely, and floating freely in the vitreous. Divergent squint; marked ciliary injection; tension + 1.

The patient was advised to have the eye enucleated, but positively refused to allow it. It was then proposed to him that an attempt should be made to remove the lens, and to this he consented. Owing to the existence of pronounced valvular and hypertrophic disease of the heart, it was thought unwise to administer any anæsthetic, and the operation was done with the patient seated in the operating chair. The usual upward section was made in the cornea, the apex being in clear cornea. The iris prolapsed at once, and this apparently prevented prolapse of the vitreous. Owing to the complete disorganization of the vitreous, it would seem as if any pressure from below would cause extensive prolapse of the fluid vitreous. The prolapsed iris was therefore carefully replaced, and a wire spoon was then gently introduced through the wound and pupil and behind the lens. Slight pressure backward against the lower part of the eyeball brought the lens into the hollow of the spoon, and it was then readily removed, followed by a prolapse of the iris. Gentle irrigation of the iris and eyeball was then done; the iris was replaced, and a pressure bandage applied for twenty-four hours. The ciliary irritation and injection in this case remained for nineteen days without any visible improvement, after which date the case healed in the usual manner, but with incarceration of the iris. There was, of course, no improvement in vision.

Case VII.—Francis E. R., aged twenty-three, November 2, 1885. Patient had lost the sight of the right eye twelve years before by a blow from a ball, but since then it had given him no trouble, except for the cosmetic defect. He had been advised to have the eye removed, but his father was unwilling to permit it. At times the opaque, dense white lens would appear in the pupil and caused an unsightly appearance.

R. E., perception of light; cornea somewhat cloudy; iridodonesis. Lens opaque, dense white in color, and floating in the clear vitreous, but attached at one point downward and outward to the ciliary processes. Tension normal; no irritation.

L. E., $\frac{20}{20}$; normal in every respect.

The operation was done on the patient while seated in the operating chair. The usual upward corneal section was made with the narrow knife, the apex in clear cornea. The speculum was then removed and the upper lid lifted away from the eye by a wire elevator. Pressure was then made with the index finger through the lower lid on the lower part of the eyeball, directly backward, and the lens at once rose and came forward into the pupillary area. As the pressure backward was continued, the point of adhesion downward and outward ruptured, and the lens at once came almost entirely out of the corneal wound and was received in a small silver spoon. The iris, of course, prolapsed, and several drops of vitreous followed. The iris was then replaced and the eye antiseptically treated and bandaged. There was no reaction and the wound healed in three days throughout, without any prolapse or incarceration of the iris. The loss of vision, of course, remained unchanged.

Case VIII.—Nicholas E., aged fifty-six, February 18, 1886. Patient was struck in the right eye by a ball three weeks before.

R. E., $\frac{9}{200}$; irregular and immovable pupil. Partial dislocation of the lens upward and inward; lens entirely opaque; zonule only partially ruptured; iridodonesis.

L. E., $\frac{20}{100}$; senile chorioiditis and beginning cataract.

The irritation caused by the blow was still intense, and, as the lens was entirely opaque and partially displaced, it was decided to remove it. An upward section was made entirely in the limbus, and then an iridectomy was made upward in the usual manner. The pressure made upon the eyeball by the fixation forceps had caused a partial rotation of the displaced lens upon its vertical axis, and it was thought that it might be removed in its capsule. A small wire spoon was introduced through the wound and coloboma of the iris on the temporal side of the lens, a slight lifting motion brought the lens away in its capsule, and it was removed from the eye without the loss of any vitreous. This may be considered a fortunate termination to a rather dangerous operation. The ultimate vision was somewhat improved, having risen from $\frac{9}{200}$ to $\frac{20}{200}$.

Case IX.—Mrs. Catharine S., aged forty-four, July 12, 1886. This patient was struck on the right eye four days before by a piece of wood, and had lost her sight at once. She had had failing vision in both eyes for some years.

R. E., fingers at six inches. Iridodonesis; blood in anterior chamber and vitreous; lens opaque and dislocated into the vitreous.

L. E., $\frac{20}{200}$; old chorioiditis and opacities in lens and vitreous.

Nearly three months later the right eye was still injected and painful, and, as she refused to have an enucleation done, it was thought best to remove the lens.

October 11th.—The usual upward corneal section was made, but, owing to the ciliary injection, an iridectomy was not done, on account of the possible profuse hæmorrhage. Pressure upon the lower portion of the eye directly backward threw the lens at once into the pupil, and at the same time caused prolapse of the iris and the loss of some fluid vitreous. As the pressure, however, kept the lens presenting in the pupil, a blunt hook

was introduced through the wound and behind the lens, thrust into the lens, and the latter was then readily removed in its capsule, without any more vitreous being lost. The iris was then replaced and the eye dressed and bandaged in the usual way. The irritation and injection began to subside on the fifth day, and the patient was discharged on the thirty-first day, with a sound central pupil and vision $\frac{20}{200}$, with some prospect of still further improvement.

Case X.—John S., aged twenty-seven, February 7, 1887. This patient was struck on his left eye three years before by a clod of earth and lost his sight at once. The eye was inflamed and painful for nearly two months, but since then has given him no trouble.

R. E., $\frac{20}{30}$ + ; faint corneal macula.

L. E., V. = 0. Tension — 1. Discolored and fluttering iris; pupil central; lens opaque and floating freely in vitreous, attached by a single narrow band downward to the ciliary processes.

March 4, 1887.—The usual upward corneal section was made, the patient being seated in the operating chair. As the knife completed the section and the aqueous escaped, the lens presented in the pupil, the upper margin nearly touching the cornea. A blunt hook was at once introduced, engaged in the lens, and the latter was removed in its capsule without the slightest difficulty. The prolapsed iris replaced itself at once, and not a single untoward symptom appeared in the course of the case, the patient being discharged on the fifteenth day.

Case XI.—Daniel F., aged sixty-four, April 4, 1887. This patient was struck one month ago on the right side of the nose and superior orbital margin of the right eye with a stone. The right eye became inflamed at once and has remained so ever since, with frequent attacks of very severe pain.

R. E., $\frac{3}{200}$; marked ciliary injection; tension + 1; iris dilated and discolored; very shallow anterior chamber; lens opaque and dislocated into the vitreous; condition glaucomatous.

L. E., $\frac{20}{20}$; slight opacity at periphery of lens; normal fundus.

April 6th.—Operation for removal of the lens. Corneal section upward entirely in limbus. Broad iridectomy upward, followed by profuse hæmorrhage, which filled the anterior chamber and checked the further steps of the operation for a time. After the hæmorrhage had been stopped by cold applications and part of the blood had been removed from the anterior chamber, the lens was found tilted forward, its upper margin lying in the pupil and resting against the cornea. It was at once removed in its capsule with a small spoon and with no loss of vitreous. The healing process in this case was very slow, and, although the wound was clean and there was no prolapse of the vitreous, the wound did not close for nearly three weeks. Vision improved somewhat, having risen to $\frac{10}{200}$.

Case XII.—Frederick G., aged fifty-six, February 19, 1888. This patient received a blow on the right eye from a hard rubber ball in October, 1887, and lost the sight of this eye at once. The sight of the other eye had previously markedly failed from the growth of a cataract.

R. E., perception of light; iridodonesis; lens dislocated entirely into the vitreous and lay tilted forward, its upper margin resting on the iris and just appearing at the pupillary edge; eye quiet; tension normal.

L. E., $\frac{20}{200}$; cataract.

February 24th.—The patient was seated in the operating chair and the usual upward corneal section made, the apex in clear cornea. There being no prolapse of the vitreous, a delicate blunt hook was introduced through the wound, passed through the pupil and behind the lens, and by a single twist penetrated the capsule and caught the lens. The lens was then drawn through the pupil and out of the lips of the wound, inclosed in its capsule, and without any loss of vitreous. The wound healed readily under the usual antiseptic dressings, and without either prolapse or incarceration of the iris. There was no improvement of the vision, and the vitreous remained cloudy as long as the patient was under observation.

Case XIII.—Mary O'B., aged thirty, February 25, 1889. Patient was struck on the right eye six months ago by a blow from a fist and lost the sight at once. She had always been quite myopic, but had never worn glasses.

R. E., perception of light; pupil irregularly oval in shape and displaced inward toward the nose; iridodonesis; lens dislocated downward into the vitreous; tags of broken adhesions on the posterior surface of sphincter margin of iris; floating opacities in vitreous; tension normal.

L. E., $\frac{20}{200}$, with sph. — D. 2·50 = $\frac{20}{70}$; large annular posterior staphyloma and patches of chorio-retinitis disseminata.

An upward corneal section was made, the apex in clear cornea. The speculum was then withdrawn and the upper lid held away from the eye by an elevator. Pressure was then made on the lower part of the sclera directly backward by the finger against the lower lid. The iris prolapsed at once, and the lens appeared in the field of the pupil. Every attempt at further pressure caused prolapse of the vitreous without advancing the lens in the slightest degree, and this method was therefore abandoned. Keeping the lens in the field of the pupil by moderate pressure below, a delicate wire spoon was introduced through the corneal wound and behind the plane of the iris, gently insinuated behind the lens, and then withdrawn, bringing the lens in its capsule with it. The iris was then replaced and a drop of a solution of eserine was instilled, and the eye dressed and bandaged in the usual way. There was but little vitreous lost, and the eye healed with very little reaction, but with a rather extensive incarceration of iris in the inner lips of the wound. There was no improvement in vision.

TWO CASES OF NASAL HYDRORRHŒA.*

By T. MELVILLE HARDIE, B. A., M. B.,
PROFESSOR OF RHINOLOGY AND LARYNGOLOGY IN THE POST-GRADUATE MEDICAL SCHOOL OF CHICAGO.

WITH A REPORT ON THE EYE SYMPTOMS,
By CASEY A. WOOD, M. D., C. M.,
INSTRUCTOR IN OPHTHALMOLOGY AND OTOLOGY IN THE SCHOOL.

Case I.—Mary S., aged forty-three, German, married, has one child, aged fourteen, healthy. Until nine years ago, when she came to America, she had always enjoyed good health. After living for two weeks in a basement, in February, 1881, she developed a cough, which became asthmatic some time between March and July. She had had occasional attacks of asthma ever since, particularly in cold, damp weather. In July she received what her medical attendant told her was a sunstroke, which confined her to bed for some time. Some pills prescribed caused a buzzing in the ears with deafness for several days (quinine?), and during the severe headaches, usually vertical, from which she has suffered at intervals since that time the deafness occasionally recurs. In August or September, 1881, a watery discharge from the nose commenced, the conjunctiva being reddened and lacrymation profuse at the same time. The discharge lasted for three or four days, stopped for a month, came on again for a few days, and again intermitted. Similar periods of discharg

* Read before the Chicago Medical Society, July 7, 1890.

and absence of discharge alternated continuously until about two years and a half ago, since which time the discharge has occurred daily, usually for three or four hours in the morning. The patient reports that it begins just as soon as she rises in the morning, whether that be at 4.30 or 6.30. Excepting on one or two occasions, no discharge has been noticed at night. She can not remember whether the discharge occurred on days on which she was confined to bed. Has never attempted to stop the discharge by lying down in the morning after the commencement of the flow. As a usual thing the fluid comes from both nostrils (sometimes from one), and drop by drop. Shortly before stopping for the day the clear water, whitish and opalescent when in quantity, becomes thicker and viscid, resembling ordinary mucus. Sneezing and formication are somewhat frequent accompaniments of the discharge, but they are by no means constant, nor does the formication appear to precede the discharge, as one might expect. It quite as frequently follows. The patient avers that this symptom has been more annoying since treatment was begun. While the asthma is ordinarily troublesome only in cold and damp weather, she is not sure that the hydrorrhœa is appreciably influenced by matters meteorological. Has not noticed that it is worse on damp days. Thinks it is as bad in July as in November. It varies in amount from time to time, but without reason, so far as the patient could determine.

History since coming under Observation.—In October, 1889, "could not see to sew," and attended Dr. Coleman's eye clinic, where glasses were prescribed. She was then referred to me. Examination of her nose showed slight posterior hypertrophy of the right inferior turbinated and a dropsical condition of the middle turbinated bodies right and left. Ridge on septum high up on left side. No polypi. Sense of smell unimpaired. No marked departure from normal sensibility of nasal mucous membrane as tested by probe. Satisfactory posterior rhinoscopic view not obtainable, tongue depressor causing gagging. Patient says this is produced by holding anything (*e. g.*, candy) in the mouth for a minute even, but she has no such sensation when masticating and eating ordinary food.

General health not very good. Burning pain in epigastrium after eating not infrequent. Painful and hyperæsthetic spot over the left eighth rib in front, which first became painful five years ago. No neuralgias. Is being treated in gynæcological clinic for laceration of the cervix. The patient has been treated during the past ten years by a sufficient number of regular practitioners and quacks, but without marked benefit. The removal by snare of portions of the middle turbinated bodies, with the internal administration of zinc oxide (gr. ½) and belladonna extract (gr. ¼), markedly diminished the flow for a time. Treatment was begun on the 10th of April, with good results until the 6th of May, when a day and night discharge commenced. This lasted until the 9th of May, the patient getting but little sleep in the interval. The nasal discharge was accompanied by a flow from the eyes and a severe headache. On the 10th and 11th of May she had asthma; there was no discharge or headache. She was then almost free from any unpleasant symptoms until the 3d of June, since which time she has had an almost daily recurrence of the discharge until the present time (7th of July), with asthma and headache from time to time. Patient's attendance has been very irregular since the beginning of June.

In view of the not infrequent association of optic-nerve atrophy with nasal hydrorrhœa (seven cases are recorded), a careful examination of the eyes was made at my request by Dr. Casey Wood, whose report is appended.

The fluid had a specific gravity of 1·006, contained chlorides, traces of mucin, a few cells from the olfactory region, and an occasional flat epithelial cell. It was feebly alkaline in reaction.

Case II.—I am indebted to Dr. Lackner for the discovery of the case whose history I shall now give.

Mrs. K. K., German, aged forty-two, married, two children, gave a history of profuse watery discharge from the nose which has lasted for ten years. Six months before the discharge began the patient suffered from "malaria" when living in a basement tenement. The flow was at the beginning not very profuse, but in a short time was troublesome throughout the day and frequently all night as well. She was often wakened by it, and it was occasionally so profuse as to prevent sleep altogether. The intermissions have been rare and of short duration. Patient asserts that the dropping has never ceased for twenty-four hours during the ten years, the amount of the discharge being about the same summer and winter. Upper lip swollen and excoriated. Watery discharge from eyes with occasional conjunctival injection. Fundus normal, no optic-nerve atrophy, and no contraction of visual fields. Dr. Wood kindly made the examination of the eyes in this case also. A troublesome and prominent symptom was sneezing, "forty or fifty times a day" being the usual thing. Unfortunately, the fluid was not examined, the discharge ceasing before the patient followed instructions in the matter of collecting it. The patient does not know the amount of the daily discharge, as she never collected it, but the constant dropping interfered very much with her work. Examination of the nose showed polypi right and left, and polypoid thickening of both middle turbinated bodies.

Treatment was begun February 25th. Polypi removed.

March 8th.—Marked lessening of discharge reported. Remaining polypi removed.

12th.—Discharge very slight. No sneezing.

May 6th.—The same. Hypertrophy of right middle turbinated snared.

17th.—No discharge. No sneezing. Snaring left middle turbinated. Patient reported absence of nasal symptoms on May 22d, June 5th, 12th, and 19th. To report again in one month.

The chief interest in the discussion of hydrorrhœa centers in its ætiology and in the fact of the occasional presence of marked eye complications. The literature of the subject is by no means extensive; about twenty-five cases are reported, and, as in a number of instances for some reason or other an examination of the nose was not made, it is perhaps hardly possible as yet to formulate a theory applicable to all cases. In fact, a perusal of the histories of cases in which a continuous discharge of water from the nose was a symptom will compel one to conclude that it may, like atrophy of the optic nerve, be produced by a great many different conditions. One was evidently due to fracture of the base of the skull (Vieusse's case*); it is an occasional accompaniment of general anasarca (Rees†); of meningitis (Paget‡); of trifacial paralysis (Althaus#); of hydrocephalus internus (Leber,‖ who thought there had been bone absorption from pressure with escape of the

cerebro-spinal fluid from the opening thus formed); while in some cases (Priestley Smith's,* Nettleship's †) the brain symptoms appear to have been very marked. In two cases, on the other hand, reported by Bosworth,‡ to whose valuable paper on the subject I have to acknowledge my indebtedness, there was at the beginning apparently no visible nasal or other disease, and, presuming the examinations to have been accurate, the affection can not very well have been anything but a paresis of the sympathetic vaso-motor nerves, as Bosworth concludes. A somewhat novel idea as to the ætiology of this affection has been suggested by Mules,# who reports three cases in support of his theory that "the dropping is due to overdistended lymph vessels of the pituitary membrane, which by their bursting cause fistulous openings." Briefly they were: 1. A girl who suffered from a discharge of fluid from the umbilicus for six months; no fistula, this discharge being followed by a similar flow for four weeks from under right upper eyelid at frequent, though irregular, intervals during day and night. Stimulation of the lacrymal gland produced no effect. 2. A boy who had congenital lympho-angeioma of conjunctiva. 3. A woman in whom a lympho-angeioma just inside sphincter ani caused diarrhœa, which alternated with watery discharge from fistulous openings in tumor. In six weeks after ligation of the tumor an apoplectoid attack occurred which caused permanent paresis of one side.

We have not far to look to see Mules's explanation of the discharge from eye and nose, but are as far as ever from knowing the cause of the enlarged lymph tubes. As a corollary to his theory, Mules concludes that the coexistence of optic-nerve atrophy with an abnormal watery secretion from eye and nose is merely a coincidence. He explains the occurrence of the atrophy by suggesting that it may sometimes be due to the wasting character of the general disease, of which it and hydrorrhœa happen to be symptoms. In some cases of hydrorrhœa there is no atrophy, just as in other cases of atrophy there is no hydrorrhœa. Before, however, any conclusion can be arrived at respecting Mules's theory, more exact knowledge with regard to the distribution of the nasal lymphatic system is required. In my opinion the affection is, with few exceptions, immediately dependent upon a vaso-motor paresis, however that may be brought about. For this Bosworth has made out a good case. With some of his conclusions, however, it is difficult to coincide. I fail to see, for example, why the general resemblance of nasal hydrorrhœa in many particulars to hay fever should lead us to assert an atmospheric factor in its causation. In my first case the appearance of the interior of the nose would have been consistent with the hypothesis that there was a distention of the mucous membrane by lymph, or that we had to do with a lymph-angeioma. The fluid could be seen to ooze from the mucous membrane of the upper part of the septum, and from the swollen opalescent middle turbinated body opposite. The discharge did not come from a polypus, so far, at any rate, as concerned that oozing from the septum; nor was the opalescent polypoid-looking middle turbinated a polypus. It became much smaller upon use of cocaine and pressure with a probe. The theory that the discharge is invariably connected with polypi has been several times shown to be incorrect. Cerebral symptoms likewise are frequently absent, as in Case II.

An interesting occasional accompaniment is asthma, as in Case I. So far as I have seen, it has not been noted as a complication of other cases of nasal hydrorrhœa, but the frequency of its association with hay fever, and the general resemblance between the latter and such apparently uncomplicated cases of nasal hydrorrhœa as the two reported by Bosworth, would at any rate prevent our surprise at such a complication. It will be noticed that the patient reports that the asthma had troubled her chiefly during the winter months, and that its onset did not, so far as she had noticed, affect the nasal discharge. My notes of the case since it came under my observation do not exactly corroborate the patient's statement; for instance, during the latter half of April the discharge was very slight and asthma absent, although headache was, perhaps, worse than usual during a part of the time, but on May 6th (when the discharge had been absent for ten days) began one of the worst of her attacks, which was accompanied by headache. This gave way on the 10th and 11th of May to asthma; then, on the 12th to the 15th of May, a very slight discharge occurred in the mornings, followed again on the 16th by slight asthmatic attacks. After that, as reported before, there was absence of both unpleasant symptoms until the 3d of June. There was then apparently an alternation between the attacks of hydrorrhœa and of asthma, but as this does not correspond exactly with the patient's recollection of the previous course of the disease, and as the number of the observations is so small, I shall merely record the fact without further comment. I may say that I have in the present history neglected to discuss the relation which the so-called neurotic temperament bears to the disease. One reason for my omission may be found in the following facts: (1) Case I was that of an individual who would nowadays be denominated neurotic; (2) Case II would not in my opinion be so named. The deduction is obvious.

While the presence of asthma was perhaps the most noteworthy feature of the first case, the second is worthy of record for a different reason. In it we had the two facts (1) that polypi were present along with the discharge, which is by no means unusual; and (2) that treatment directed to the removal of these polypi, and of those portions of the middle turbinated in which there was polypoid degeneration, was efficient in stopping the discharge, and that, too, in cold and wet weather—a very unusual termination to a long-standing case of nasal hydrorrhœa.

I think we may conclude, from a careful reading of the cases recorded, that nasal hydrorrhœa is not a disease *per se*, but a symptom of many pathological lesions, and that the prognosis and treatment of each case must be determined by conditions aside in the majority of instances

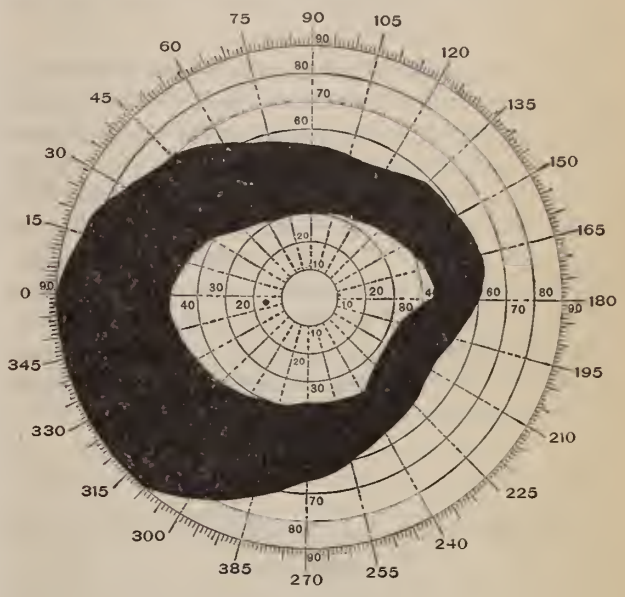
from the mere fact that there is a flow of water from the nose.

M. S. has complained of weakness of sight, chiefly during the past eight months. Last November glasses were prescribed for her, which, however, she did not think enabled her to see any better. She suffers from bilateral epiphora, which is usually, though not always, worse in the morning. It then amounts to a continual flow from both eyes of a fluid resembling tears, and, generally speaking, is worse when the discharge from the nose is worse. During the daytime, also, when the nasal flow is lessened or stops altogether, there is very little lacrymation. The flow of tears has never produced excoriation of the lids. In November last V. R. $= \frac{15}{200}$; V. L. $= \frac{15}{40}$. She was then wearing R. + 3 D., and L. + 1·75 D., which on trial were found not to improve the visual acuity. Both adduction and abduction were weak, the former showing at one trial a strength of 4°, at another 8°. The interni muscles could overcome a prism of 19°–23° only. At that time she complained of photophobia, and of dark spots in front of her eyes—in front of the right eye especially—and she thinks that for a time at least she was so blind that she could barely discern large objects. Then, for a while, her vision improved, but it has never since been normal, nor is it possible by correcting her refractive error (compound hyperopic astigmatism) to greatly improve the visual acuity. The conjunctivæ, both ocular and palpebral, are injected, but there is no purulent or muco-purulent secretion from the lids, and they do not adhere in the mornings. The last examination made shows a marked improvement (in the right eye particularly), as V. R. $= \frac{20}{40}$, and V. L. $= \frac{30}{40}$, both with correction. The *puncta lacrimalia* are patent and in normal position. There is no affection of either lacrymal sac, and no indication of obstruction of the nasal duct. The ocular excursions are of normal extent on both sides and in all directions. Pupils are both active to light and accommodation. Tension normal in both eyes. The

RIGHT EYE.

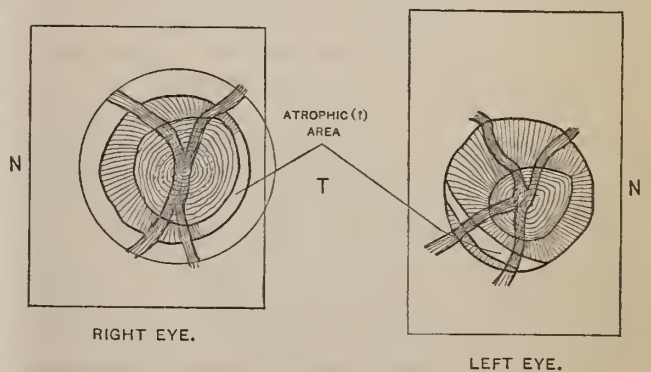
patient does not now complain of scotomata, only of weakness of vision and of inability to read or to do near work with comfort. These, and the other ocular symptoms, have not to any appreciable degree been relieved by atropine or by a full correction of her refractive error. A further examination of the case reveals the fact that she is not color-blind, and that she has no color scotomata. Both fields of vision for white, taken by means of a McHardy perimeter with a 5 mm. square object, are shown in the charts. These charts were carefully worked out several times, and the contractions were found to be fairly regular and symmetrical. This regularity is especially seen in the left eye, as the right field is more restricted toward the nasal side than was found to be the case in the left eye. The field for red is correspondingly limited in both eyes.



LEFT EYE.

The fundus appearances are interesting, although there is nothing abnormal outside of the papillæ. The *right disc* is deeply and centrally excavated, and the blood-vessels come forward in a normal manner, but the whole papilla is very slightly paler than it should be. On the nasal border of the nerve there is a narrow, yellowish-white band, forming in that situation the rim of the physiological cup, and occupying about one third of its circumference. A somewhat similar appearance is to be seen in the *left disc*. Here there is no general pallor, and the

DIAGRAMS OF OPTIC DISCS.



normal cupping is shallow. At its bottom, however, the stippling of the cribriform fascia is to be seen. A band, yellowish-white in appearance, longer than but quite as narrow as that visible in the right disc, occupies the lower outer aspect of the left papilla. It does not extend, as in the former case, to the edge of the excavation toward the nerve center, nor does it reach in part of its course the outer rim of the disc. I have endeavored to illustrate this condition of things by the above rough diagrams.

I have seen a number of similar whitish areas in papillæ of eyes otherwise normal which were not accompanied by deterioration of vision or contraction of the field of vision, and I consequently hesitate to regard this picture as evidence of atrophic changes, however limited, of the optic nerve itself, and yet they are certainly not the pale spots on the surface of the disc which one sometimes sees due to variations in the light reflex from an uneven papillary surface.

Whether the limited decolorization of the discs is evidence of a retro-bulbar neuritic process it would be difficult to say. The history of an attack, occurring six months before and accompanied by absolute central scotomata and great loss of visual acuity, certainly points in that direction, but, in the absence of more positive proof, one can not very well decide. If such has been the case, it is not easy to say why, with some remaining impairment of vision, there are no central scotomata, not even for colors.

Notwithstanding all treatment, the ocular symptoms since the date of writing the foregoing, the epiphora especially, are as pronounced as ever.

A CASE OF MYXOMA OF THE EPIGLOTTIS.*

By S. O. VANDER POEL, M. D.

The rarity with which myxomata present themselves in the neighborhood of the larynx, and the fact that but few cases have been placed on record, have induced me to bring before you for consideration the study of this form of benign growth, and the recital of a case which has recently come under my observation.

The patient, a German, fifty-four years of age, by occupation a blacksmith, was perfectly well until seven months ago, when he began to notice failing strength and loss of flesh. Some weeks later his throat commenced to annoy him; there was difficulty in deglutition, with the sensation of a foreign body in the throat. As he expressed it, "an obstruction to the passage of food, and a tendency for it to go the wrong way." At no time was any actual pain complained of. Talking was an effort and was carried on with fatigue, amounting at times to actual distress. Only occasionally was there hoarseness, and then after prolonged use of the voice. It then might more properly be described as a feeble whisper which it was difficult to understand. Occasionally the peculiar staccato inflection was noticeable. At night there were suffocative attacks, when he would awaken suddenly from his sleep with the feeling of great apprehension and the sensation of strangling. Of late these attacks have been more frequent, and would seem to be produced by some mechanical obstruction to the entrance of air. When he first came under observation at the Throat Department of the Manhattan Eye and Ear Hospital on the 17th of March last he was emaciated, and, from a large and powerful man, had become a weakly invalid, who walked with effort and apparent distress. This condition he ascribed to the small amount of nourishment he had been able to take of late, as he could swallow but liquid food, and that in small quantities. A harassing cough had been present for some months, and considerable difficulty was experienced in expectorating the mucus which gathered in the throat. He complained of an intermittent pain in the cardiac region. Physical examination disclosed a loud blowing mitral murmur heard over the entire sternum, with dilatation of the left ventricle. The lungs were emphysematous, with evidence of chronic bronchitis. Respirations, 28 to 30; pulse, 90. Rhinoscopic examination revealed some slight hypertrophic rhinitis, the left middle turbinated body being in contact with the septum, together with an ecchondroma of the septum of the right side, but nasal respiration was not materially interfered with. With the laryngeal mirror a tumor of a yellowish-red color, translucent, of about the size of a horse-chestnut, was seen springing from the lingual side of the epiglottis; the surface was glistening, lobulated, and traversed by numerous small vessels. It was attached by a broad base to the glosso-epiglottic fossa of the left side. It occupied so much space in the pharynx and pressed the epiglottis to such an extent that only a small portion of the laryngeal image could be seen. Palpation with the laryngeal probe and finger showed it to be of soft consistency, and imparted the sensation of fluctuation. By elevating the neoplasm, the right free margin of the epiglottis could be distinguished with the finger, but, in passing over to the left border, the free edge of the epiglottis was lost in the growth. From its consistency, color, and general conformation, an epiglottic cyst was diagnosticated, but aspiration failed to withdraw any fluid. It was accordingly decided to remove the growth with the galvano-cautery snare. This was done under cocaine anæsthesia the following day. Twenty-five minutes were occupied in the operation, which was accomplished with little difficulty and no hæmorrhage. It was found to have been attached by a broad base to the entire left lateral half of the lingual side of the epiglottis. It resembled an adenoma, its surface being lobulated and traversed by fine capillary blood-vessels and inclosed in a fibrous capsule. It was submitted for microscopic examination to the pathologist of the hospital, to whom I am indebted for the following report: The capsule inclosing the tumor is about 1 mm. in thickness, and is composed of mucous membrane that in no way differs from the ordinary membrane covering the epiglottis. This envelope, which can be readily stripped from the tumor, is covered by stratified pavement epithelium, the underlying membrane being fibrous tissue of loose texture, containing a network of numerous and wide lymphatics. The mucosa is dense, and projects, in the form of numerous small papillæ, into the epithelium. A network of capillary blood-vessels is distributed in the superficial portion of the mucous membrane. The substance of the tumor proper conforms to the description of hyaline myxomatous tissue. In the hyaline ground substance, which is composed of a fibrillary connective-tissue network of extreme delicacy, are imbedded the characteristic stellate cells, some of which anastomose by their prolongations, while others again are without any processes, being nearly round. Pure myxoma is so uncommon that several sections were made in different portions of the tumor to ascertain if some sarcomatous tissue might not be present. They all, however, presented the same structure as described above. The growth is therefore a pure hyaline myxoma. [Signed: Ira Van Giesen, M. D., Laboratory of the Alumni of the College of Physicians and Surgeons, New York.]

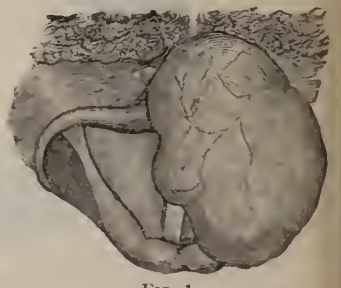


Fig. 1.

* Read before the American Laryngological Association at its twelfth annual congress.

There were no inflammatory symptoms in the throat following the operation, and in the course of two days the patient could swallow without pain or discomfort. His appetite and strength, however, failed to return, and, there being a lurking suspicion of some malignant trouble elsewhere, he was advised to place himself in the German Hospital, where he came under the care of Dr. Isaac Adler. From the notes taken after his admission to the hospital, we find that several examinations of the blood were made which showed a marked degree of anæmia; in one cubic millimetre of blood there were but 1,000,000 red corpuscles and 400,000 white. The corpuscles were of normal size and shape. The spleen was normal and there were no glandular swellings, except some slight cervical enlargements. In the washings of the stomach after a test meal no hydrochloric acid was found, which tended to confirm the diagnosis of cancer. The urine contained traces of albumin but no casts. After the lapse of several weeks a slight recurrence of the growth on the epiglottis was noticed; it occupied the seat of the original tumor, was slightly elevated above the surface, and of a dark color.

FIG. 2.

The patient gradually sank, and died in the first part of May. On autopsy, all the organs were markedly anæmic; the lungs were found to be emphysematous, with evidences of chronic pleurisy. The heart muscle was anæmic and fatty. Endocarditis existed which had resulted in mitral stenosis, the left ventricle being dilated. Slight parenchymatous nephritis, one kidney being red and the other white. The mucous membrane of the stomach was atrophied and the organ slightly dilated. The liver was somewhat shrunken and anæmic, but otherwise normal. Spleen normal. In no organ was there found any evidence of cancerous disease.

The fatal termination of this case would seem to be only indirectly due to the throat lesion, for, as the growth was surely of a benign nature, it could only have affected the issue by the inanition it caused previous to its removal. The cause of death, then, should be ascribed to pernicious anæmia, as this was undoubtedly present, as is evidenced by the diminution in the number of red corpuscles from 5,000,000, the normal number, to 1,000,000—while the white corpuscles were present in their normal proportion, about 400,000; also by the fatty degeneration of the heart muscle, the endocarditis, and dilatation of the left ventricle, and finally the atrophic changes found in the mucous lining of the stomach. Although pernicious anæmia has no symptoms that may not occur in other forms of anæmia, there are, nevertheless, certain symptoms which, especially in combination with each other, are more frequent in the pernicious than in the secondary or symptomatic anæmias. These symptoms, which, therefore, are in a degree characteristic, although not pathognomonic, of pernicious anæmia, are an excessive degree of anæmia; the preponderance of the anæmia over all other symptoms; the progressive and malignant course, often uncontrolled by therapeutical agents; the absence in many cases of emaciation, the intensity of heart murmurs without valvular lesions, and the frequent prominence of digestive disturbances. Upon post-mortem examination, fatty degeneration of the heart, and at times certain changes in the marrow of the bones, are observed with a greater degree of constancy and of intensity in pernicious than in symptomatic anæmia. The clinical history of our case taken in its entirety is therefore sufficiently characteristic to justify us in making the diagnosis of pernicious anæmia.

Pernicious anæmia and pseudo-leucocythæmia are frequently associated with, or rather accompanied by, new growths located in different portions of the body. These vary greatly in their size, location, and anatomical characteristics. Mosler, in the course of an article on Pseudo-leucocythæmia in Ziemssen's *Encyclopædia*, calls attention to them: "The follicles of the tongue and tonsils are sometimes much enlarged, which are whitish and pulpy on section; also upon the surface of the epiglottis soft, shiny, and translucent nodules, varying in size from a pea to a hazel-nut, at times single and again multiple, have been found." They project above the surface and interfere more or less with the function of the part, according to their size and location. Thus pressure upon the larynx or trachea may obstruct respiration, and death in pseudo-leucocythæmia is sometimes due to suffocation from this cause. So also paralysis of the laryngeal muscles may be caused by pressure of one of the growths on the laryngeal nerve. These growths are by no means confined to the respiratory tract, but are scattered through the body in various situations; for instance, the pneumogastric nerve may be involved in a tumor and the action of the heart be retarded; the femoral vein may be compressed and œdema of the lower limb follow; jaundice has been attributed to pressure on the bile duct, etc. It is, then, to this class of tumors that our case properly belongs. It differs in some respects from those cases of laryngeal myomata already reported—in the first place, by being associated with pernicious anæmia and terminating fatally, and in the second by the recurrence that took place. In a review of the literature of the subject we have been able to find but few cases of this form of benign tumor recorded, if we exclude those in which no microscopic examination was made. Sir Morell Mackenzie observed one on the right vocal cord that also had certain mucous characteristics. Bruns reports a case of pure hyaline myxoma which was attached to the right wall of the larynx, was of an irregular pear-shape, yellowish-red in color, dense but elastic in consistency, and almost completely occluded the entrance to the larynx. J. Solis-Cohen, in the *Transactions of the Pathological Society of Philadelphia* for 1873, mentions a myxomatous growth which he removed with forceps. It was multiple and pedunculated, attached apparently to the anterior portion of the thyreoid cartilage just below the glottis and to the left of the middle line. The growth was distinctly lobulated. The characteristic stellate cells, some anastomosing, imbedded in a hyaline ground substance, were shown upon microscopic examination. Tauber has operated upon one case of hyaline myxoma which was attached by a broad base to the entire anterior or lingual surface of the epiglottis. Thompson and M. Schmidt have had similar cases. Eemann, in the *Revue de*

laryngologie for February, 1889, reports two cases, both of which were located on the vocal cords. These cases, together with the one here related, make a total of nine—certainly a small showing when we consider the immense number of laryngeal neoplasms yearly recorded. The differential diagnosis of these growths *in situ* from cystic tumors, and at times from fibroma, is most difficult if not impossible. Eemann states that he made an error in diagnosis in both of his cases. Basing his diagnosis on the consistence, color, and transparency of the growths, he thought they were cysts until the microscope showed them to be hyaline myxomata. This fact would seem to arouse the suspicion that perhaps many cases that have heretofore been classed as cysts in reality, if microscopic examination had been made, would properly have come under the head of myxoma. Would it not, therefore, be fair to assume with Eemann that it has not been scientifically proved that hyaline myxomata are so uncommon as we have hitherto been led to suppose?

Acute Yellow Atrophy of the Liver.—"Dr. Rosenheim reports a case of acute yellow atrophy of the liver in a child of ten in which crystals of bilirubin were found in the urinary deposit. These crystals have never, as far as Dr. Rosenheim is aware, been found before, except in the urinary tubules in icterus neonatorum. There was no albumin in the urine, only traces of propeptone and no peptone. Evidence was found of a considerable amount of degenerative change in the kidney parenchyma by the existence in the urine of granular casts. Epithelial remains and globules of fat were also found. As regards the ætiology of the disease, Dr. Rosenheim is not inclined to share in the view of Klebs and Eppinger, by whom acute yellow atrophy is looked upon as an infectious disease produced by special microbes, because he was unable to detect any micro-organisms in sections of the liver, and his endeavors to obtain cultures failed. He is much disposed to ascribe importance to the finding of masses of bacteria in the blood circulation, in consequence of which pathological changes in the liver may be set up. He is himself inclined to think that bacteria whose habitat is unknown produce some chemical body which exerts a deleterious effect on the parenchyma of the liver, and produces the characteristic morbid changes of acute yellow atrophy."—*Lancet.*

The Microbes of Pneumonia.—"Dr. Quelsner has examined the lungs of a number of children and adults dying from pneumonia, his results showing that the pneumonia coccus of Fränkel and Weichselbaum is the usual bacterial cause of true croupous pneumonia. This coccus was also found in the majority of cases of broncho-pneumonia. In both children and grown-up people the sputum contained the coccus at the very commencement of the lung affection, and its existence appeared to form a very good sign of the invasion of pneumonia of one kind or another. In the lungs of ten children who had died of various forms of pneumonia, primary as well as secondary to measles, diphtheria, and tuberculosis, Friedländer's pneumonia bacillus was not once found, but the coccus was found in eight cases. In several instances it was impossible to distinguish between the catarrhal and the croupous form, as even in undoubted catarrhal cases a very perceptible quantity of fibrinous exudation was found."—*Lancet.*

Glucose as a Diuretic.—"According to Mlle. Sophie Meslach, lactose is not the only diuretic sugar. Glucose acts in the same way. Lactose is only absorbed in the form of glucose; it acts solely on the kidneys, but does not pass into the urine. Its effect is to raise the quantity of urine higher than the quantity of fluid swallowed. It gives good results when the kidneys are healthy or nearly so; in dropsy of cardiac origin also, when there is only a small proportion of albumin in the urine. The dose is 200 grammes of syrup at 75 per cent. a day. The grape cure so general in Switzerland and Germany acts in virtue of the glucose."—*British and Colonial Druggist.*

THE

NEW YORK MEDICAL JOURNAL,

A Weekly Review of Medicine.

Published by D. Appleton & Co. Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, SEPTEMBER 6, 1890.

THE CONNECTION BETWEEN GASTRIC DISEASE AND DISORDERS OF THE NERVOUS SYSTEM.

According to the opinions of M. Cuffer, expressed in a recent number of the *Revue de médecine*, reflex action can not explain the persistency with which nervous disorders appear in connection with diseases of the stomach. In chronic gastric cases, notably in those of cancer, he has observed the presence of these disturbances, and he considers it possible that they may depend upon an ascending inflammation of the pneumogastric nerve, extending to the bulb, and on this supposition he explains the bulbar symptoms which he has found present in his cases during life, and which post-mortem examination has enabled him to verify. In the early stage of disease such manifestations have, no doubt, a reflex origin, but the researches carried on by the writer in connection with tabes dorsualis have led him to observe the fact that reflex disturbances have great prognostic value and that they indicate the direction which will eventually be taken by the concomitant nervous lesion.

Nervous disorders of gastric origin may be divided into two classes: 1. Transient disturbances of variable intensity, sometimes intense, but leaving no permanent trace behind them. 2. Permanent affections, always grave, bringing about disease of sufficient gravity to cause death. Of the first class stomachal vertigo is a frequently observed instance, but it is found more commonly in cases in which the mucous membrane of the stomach is alone concerned, and not in those in which the whole thickness of the gastric wall is involved, as is particularly the case in cancer. But it is grave structural lesions that are dealt with in M. Cuffer's paper. Coincidently with the beginnings of disease, reflex disturbances occur, and respiration and cardiac action are disturbed, but after a certain period the right heart becomes permanently dilated, and the signs of tricuspid regurgitation with intermittence become apparent. Visceral congestions and œdema of the extremities also occur, and in this way patients whose disease is in the stomach may die of a cardiac cause.

These phenomena are thus explained by M. Potain, who has given special attention to their production. At the moment that the gastric mucous membrane undergoes congestion a reflex influence is developed which brings about a spasm of the branches of the pulmonary artery; hence tension is increased throughout this arterial distribution and the emptying of the right heart is interfered with, so that at first it undergoes transient dilatation and later on manifests the signs of tricuspid regurgitation and asystole. A reflex action may thus give rise to grave structural disease, and even to fatal effects. Further,

the tendency to bulbar changes in gastric disease was long ago pointed out by Peter, who described, in connection with these effects, pain in the upper part of the vertebral column. Salivation is often present in such cases, a symptom essentially bulbar.

Cuffer relates four cases in support of his statements, in all of which there were stomach symptoms with evidence of organic disease, and subsequently signs of bulbar paralysis, but he was not able to prove his explanation of these coincidences until November, 1889, when he was enabled thoroughly to convince himself of its correctness at the autopsy of a man, aged forty-five, who had died in his wards at the *Hôpital Tenon*. A well-marked inflammation of the peripheral parts of the vagus was demonstrated. M. Cuffer brings his communication to a close by asserting the existence of the two kinds of nervous disturbance due to disease, functional disturbance and organic lesion which is of the nature of a bulbar myelitis consecutive to an ascending inflammation of the vagus, the latter taking its origin at the level of the gastric lesion, and which is accompanied by the symptoms, more or less complete, of labio-glosso-laryngeal paralysis. As to prognosis, the transient nervous manifestations do not increase the gravity of the situation, except in those rare cases where cardiac dilatation and asystole are present, while the permanent nervous changes indicate a rapidly fatal termination.

FALSE WEIGHTS IN PHARMACEUTICAL PREPARATIONS.

In the *Tenth Annual Report of the Board of Health of the State of New York* there is an interesting report by Professor G. C. Caldwell, the public analyst, on the examination of two hundred and seventy-five samples of alkaloidal preparations made by various manufacturers, sold by various dealers, and purchased at different times in different localities. Of these, he classed one hundred and seventy-seven as good, thirteen as passable, and eighty-five as deficient.

A review of the appended tables gives some interesting information. For instance, in fifteen samples of sulphate of quinine, foreign alkaloids were found in excess in nine specimens; and this excess is found in a manufacturer's quinine that in other specimens shows an absence of any foreign alkaloids. Of forty-two samples of capsules of quinine, twenty-two exhibited a deficiency of quinine varying from one two-hundredth to four fifths of a grain in each capsule; in twenty samples there was an excess varying from one fiftieth to one third of a grain in each capsule. In ninety-eight samples of quinine pills, seventy-one exhibited a deficiency of from one two-hundredth to one half a grain, and in twenty-seven specimens there was an excess attaining one tenth of a grain. Here, again, we find the pills of the same manufacturer showing a deficiency as great as one sixth of a grain and an excess as high as one twenty-fifth; with the products of one firm an excess was found three times and a deficiency twenty times, and, while the amount is insignificant in each pill, it makes considerable difference in the total quantity of quinine in, say, a hundred pills. So with pills of sulphate of morphine, a deficiency was found twenty-nine times and an excess five times, the former varying from one two-hundredth to one tenth of a grain, while the excess was inappreciable. All hypodermic tablets of morphine were short from one one-hundredth to one fourteenth of a grain.

These average variations were found in the products of well-known manufacturers, as well as in those of local pharmaceutists; and it is not unreasonable to question the care with which manufacturing processes are conducted, as well as the indifference to any examination of either the alkaloids used in the manufacture or the product after being manufactured, if such wide ranges of variation in the dosage of preparations from the same manufacturer can be found. We have our thermometers tested and corrected; will the competition of manufacturers render the same procedure necessary with our drugs? The work that is done by the State board in this line is excellent, and we hope that its publicity may lead to greater care in manufacturing processes.

MINOR PARAGRAPHS.

THE "WILD MELON" OF AUSTRALIA.

In the *Australasian Medical Gazette*, Mr. J. F. Souter, of Lake Cudgellico, New South Wales, records a case of poisoning with a cucurbitaceous plant indigenous to Australia, known as the "wild melon." The patient was a child, three years old. The symptoms were nausea followed by vomiting of a watery fluid; five hours later, a convulsion with opisthotonos, upward rotation of the eyeballs, and foaming at the month; and finally a comatose state with great contraction of the pupils, pallor of the face, and labored breathing, the pulse being 140 and the temperature 98° F. After further vomiting and the administration of a warm bath the pupils suddenly regained their normal size, and the child cried. Pupillary contraction came on again, and the pulse fell to 100. Two grains of calomel were then given, also frequent teaspoonful doses of brandy. This was followed by profuse sweating of short duration and by sleep, after which there was nothing noticeable about the child, except slight yellowness of the sclerotics.

NERVOUS DERANGEMENTS AFTER CASTRATION.

In the *Wiener medicinische Presse* Dr. Weiss relates the case of a man, forty-eight years old, both of whose testicles were removed for tubercular disease. The operation was shortly followed by certain psychical and nervous derangements, some of which lasted for six years. The attacks were generally preceded by an aura of a sensation of oppression, and consisted of flashes of heat about the head and trunk, accompanied with profuse sweating. At the same time there were neurasthenic phenomena, such as headache, vertigo, palpitation, and melancholy, and the memory and the will were notably enfeebled. After a short time there were attacks of gastro-intestinal neuralgia. The author likens these troubles to those observed after oophorectomy or in connection with the menopause. It is to be noted that the patient was of neurotic antecedents of an hereditary nature.

THE TOXICITY OF THE URINE IN INTERMITTENT FEVERS.

According to the *Revue générale de clinique et de thérapeutique*, Dr. Brousse has experimented on rabbits to determine: 1. The modifications of the toxicity of urine during a

paroxysm of intermittent fever. 2. The relations between the toxicity during the paroxysm and during convalescence. He has demonstrated that the urotoxic coefficient, calculated by Bonchard's formula, is elevated during the paroxysm. The physiological effects observed are those usually noted after the injection of urine: dyspnœa, myosis, fall of temperature, exophthalmia, and convulsions. The toxicity is diminished during convalescence, being much less than during the paroxysm and less than that of normal urine. It is yet to be determined whether the toxicity depends upon the febrile state solely, and also whether there is a difference in the toxicity of the urine during and at the end of the paroxysm.

DEDUCTIONS FROM EXPERIMENTS WITH DRUGS.

The *Progrès médical* states that Dr. Huchard recently read a paper on The Physiological and Therapeutical Action of Drugs before the *Société de thérapeutique*, calling attention anew to significant differences in the action of certain drugs in the well and in the sick and in various forms of disease. For example, it was stated that quinine lowered the temperature in typhoid fever, but had no such effect in erysipelas. The lesson to be drawn from such facts is that it is not safe to make sweeping therapeutic deductions from observations of the physiological action of drugs; to use the author's words, physiology should not enslave medicine.

A MODIFICATION OF ROMBERG'S TEST IN THE DIAGNOSIS OF LOCOMOTOR ATAXIA.

In a recent Bordeaux thesis, summarized in the *Gazette hebdomadaire de médecine et de chirurgie*, Dr. Perron describes a modification of Romberg's test by which he has been enabled to diagnosticate locomotor ataxia in its incipiency. The patient is directed to stand on one leg and close his eyes; if he can not keep his balance, the inference is that he is affected with a spinal lesion that will ultimately give rise to locomotor ataxia. As ordinarily employed, Romberg's test often fails in cases that are not far advanced.

PERSONAL UNCLEANLINESS AS A FACTOR IN THE CAUSATION OF CHOLERA.

In the *Gazette médicale d'Orient* Dr. Gabuzzi cites Bochefontaine's experiments going to show that the microphyte of cholera is sterile within the patient's organism, and that, in order to be rendered capable of conveying the disease, it must find a nutritive soil on being cast off from the system. The urine, he thinks, often constitutes a medium in which it may attain pathogenic powers, and uncleanliness, which favors the mixture of urine with the bacillus, may therefore be regarded as a predisposing cause of cholera.

EPILEPSY AND ANKYLOSIS OF THE ATLAS.

Epilepsy has often been observed in cases of ankylosis of the atlas, and the epilepsy has been regarded in such cases as the result of the encroachment of the bone on the vertebral canal. In an article published in the *Archiv für pathologische Anatomie und Physiologie und für klinische Medicin*, Dr. W. Sommer gives it as his opinion that such encroachment should not be considered as a cause of epilepsy unless it is accompanied by signs of compression of the spinal cord. He founds this opinion on the absence of epilepsy in the case of an anæmic old man who had ankylosis and forward subluxation of the atlas, apparently in consequence of arthritis deformans.

SIMULTANEOUS DISLOCATION OF BOTH ENDS OF THE CLAVICLE.

In *Guy's Hospital Reports*, for 1889, Mr. Clement Lucas relates a case of this rare injury. The patient, a man, thirty-two years old, was standing between the wheels of two vehicles that were close together, when a third vehicle came into collision with one of them and gave it an impetus by which the man's chest was partially crushed between the wheels. The outer end of the right clavicle was forced over the acromion, and its inner end was driven backward and downward, and lodged beneath the sternum, the first costal cartilage on each side being at the same time dislocated backward.

A MEDICO-LEGAL VIEW OF PAINLESS LABOR.

Dr. Brunon recently reported to the *Société de médecine* of Rouen the case of a primipara whose labor was so nearly painless that she herself mistook it for difficult defecation and would have been delivered in the water-closet if she had not been removed from it. According to the abstract published in *La Normandie médicale*, she felt only lumbar pains and a sense of weight in the rectum, and was not aware of the flow of liquor amnii. The author infers from this case that the discovery of a new-born infant in a water-closet pan does not necessarily raise the presumption of premeditated infanticide.

THE PHYSICIAN AS A PREFERRED CREDITOR.

According to French practice, the physician is a preferred creditor only in case of the patient's death, and then only to the extent of his fees for attendance during the last illness; but, as we learn from *Lyon médical*, a French court has recently decided in favor of the claim of a Dr. Benoist as a preferred creditor of a patient who recovered, but became insolvent. The decision overruled that of the assignee, and the costs fell upon the estate.

THE MEDICAL CORPS OF THE ARMY.

We would call the attention of our younger readers to the notice, given elsewhere in this issue, of the session of an army medical board in New York during the month of October. There is no more honorable office for a physician to bear than that of a medical officer of the United States Army, and there are few that afford him greater opportunities for entering upon a career of distinction.

THE NEW SURGEON-GENERAL OF THE ARMY.

The hope expressed by us last week has been fulfilled by the confirmation of Dr. Baxter's nomination as surgeon-general of the army, which took place at about the time our last issue went to press. Surgeon-General Baxter is very much esteemed by the profession, and we feel confident that his administration of the affairs of his high office will prove gratifying to them.

A REMEDY FOR PHTHEIRIASIS PUBIS.

According to *La Médecine moderne*, M. Brocq uses a solution of one part of corrosive sublimate in five hundred parts of vinegar as a lotion for destroying crab-lice. It is said that it not only kills the pediculi, but also detaches the nits.

ITEMS, ETC.

An Army Medical Board will be in session in New York city, during October, 1890, for the examination of candidates for appointment in the Medical Corps of the United States Army to fill existing vacan-

cies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War, before October 1, 1890, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which, his diploma must be submitted to the Board. Further information regarding the examinations may be obtained by addressing the Surgeon-General, U. S. Army, Washington, D. C.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 2, 1890:

DISEASES.	Week ending Aug. 26.		Week ending Sept. 2.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	37	11	42	11
Scarlet fever	14	3	17	1
Cerebro-spinal meningitis	0	0	1	0
Measles	79	12	52	10
Diphtheria	51	16	52	16

The New York Institute for Eye and Ear Diseases is the title of a recently incorporated institution under the medical management of Dr. J. L. Campbell, Dr. W. C. Campbell, Dr. Charles Simmons, Dr. George P. Shirmer, and Dr. C. J. Dumond. Its object is to maintain a free hospital and dispensary for the treatment of diseases of the eye, ear, and throat, and to establish a school of instruction in the treatment of these diseases.

The Mississippi Valley Medical Association will hold its sixteenth annual meeting at Louisville, Ky., on Wednesday, Thursday, and Friday, October 8th, 9th, and 10th, under the presidency of Dr. Joseph M. Mathews of that city.

The German Medical Society of Brooklyn will hold its regular monthly meeting on Friday, the 12th inst.

Bromide of Ethyl as an Anæsthetic.—"Dr. Thomas Frank, of Torontal-Szégcsány, in Hungary, has employed, it is stated, with great success the inhalation of bromide of ethyl for anæsthesia during operations on the mouth. In one case the patient, though he felt no pain during the removal of a sarcomatous epulis, did not entirely lose consciousness, as he spat some blood when requested to do so, and when at the commencement the breathing stopped, he resumed it in reply to directions."—*Lancet.*

Change of Address.—Dr. Charles W. Brown, from Elmira, N. Y., to 902 Fourteenth Street, N. W., Washington, D. C.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service for the two weeks ending July 5, 1890:*

(*Previously omitted.*)

Hutton, W. H. H., Surgeon. Ordered to Washington, D. C., for special duty. June 23, 1890.

Long, W. H., Surgeon. Granted leave of absence for thirty days. July 2, 1890.

Austin, H. W., Surgeon. When relieved at Chicago, Ill., to report in person to the Supervising Surgeon-General. July 5, 1890.

Irwin, Fairfax, Surgeon. To proceed to Biloxi, Miss., on special duty. July 2, 1890.

Mead, F. W., Surgeon. Relieved from duty at St. Louis, Mo., to assume command of the Service at Chicago, Ill. July 5, 1890.

Armstrong, S. T., Passed Assistant Surgeon. Granted leave of absence until August 7, 1890. June 24, 1890.

Kalloch, P. C., Passed Assistant Surgeon. Relieved from duty at San Francisco, Cal., to assume command of the Service at St. Louis, Mo. July 5, 1890.

Perry, T. B., Assistant Surgeon. Granted leave of absence for ten days, July 2, 1890. Upon expiration of leave to proceed to Norfolk, Va., for temporary duty. July 5, 1890.

Cobb, J. O., Assistant Surgeon. To proceed to St. Louis, Mo., for temporary duty. July 5, 1890.

Brown, B. W., Assistant Surgeon. To proceed to San Francisco, Cal., for temporary duty. June 23, 1890.

Resignation.

Armstrong, S. T., Passed Assistant Surgeon. Resignation accepted, by direction of the President, to take effect August 7, 1890. June 24, 1890.

Appointment.

Brown, B. W., Assistant Surgeon. Commissioned as an assistant surgeon by the President. June 23, 1890.

(*Omitted from previous list.*)

Bailhache, P. H., Surgeon. To proceed to Eureka, Col., and Astoria, Oregon, as inspector. June 5, 1890.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending August 30, 1890:*

Hoehling, A. A., Medical Inspector. In addition to present duties, ordered as President of Medical Examining Board at Philadelphia convened by Department Order, June 9, 1890.

Kennedy, R. M., Assistant Surgeon. In addition to present duty, ordered as member of the above-named Board.

Ogden, F. N., Passed Assistant Surgeon. In addition to present duty, ordered as member of the above-named Board.

McClurg, Walter A., Surgeon. Granted a month's leave of absence from September 1st.

Kershner, Edward, Surgeon. Granted two weeks' leave of absence from September 1, 1890.

Letters to the Editor.

"PINK-EYE."

London, *August 20, 1890.*

To the Editor of the New York Medical Journal:

Sir: In your issue for June 28, 1890, an article entitled "Pink-Eye" appears, which refers to articles by the undersigned which appeared in the *Arch. of Ophth.*, vol. xv, No. 4, 1886, and in the *Medical Record* for May 21, 1887. I wish to notice the article in your Journal only to correct some errors.

Quoting from the paper referred to: "No one has, so far as I am aware, repeated his experiments" (meaning my experiments), "nor has any one essayed to make an analysis of the evidence he has furnished."

The writer is referred to an article by Kartulis (*Ctrlbl. f. Bacteriologie u. Parasitenk.*, page 289, 1887), where he will find full confirmation of the results previously arrived at by me.

"A pure cultivation of the small bacillus could not be obtained."

Since writing the articles referred to above, I have produced a pure cultivation of the bacillus, photographs of which have been made. These were shown at the Tenth International Medical Congress in Berlin. Their existence was known to the writer of the article which appeared in your Journal before that article was published. "The small bacillus (together with the clubbed bacillus) was found in the secretion in every case."

There is no authority whatever in my article for the clause included in parenthesis in this quotation.

John E. Weeks, M. D.

Proceedings of Societies.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Twelfth Annual Congress, held at Baltimore, on Thursday, Friday, and Saturday, May 29, 30, and 31, 1890.

The President, Dr. John N. Mackenzie, of Baltimore, in the Chair.

(*Continued from page 187.*)

A Case of Myxoma of the Epiglottis was the title of a paper read by Dr. Vander Poel. (See page 268.)

The President: We often draw incorrect inferences with regard to the rarity of diseases by the infrequency of reports of such cases in medical literature. I think that, whereas this growth in the locality described by Dr. Vander Poel is rare, the same growths, occurring lower down in the larynx, are not of such rarity as might be inferred from the published records.

Dr. Swain: I remember removing such a growth from the fossa glosso-epiglottidea, just at the junction of the epiglottis and the tongue, which was a simple polypus, strictly a mucous polyp, resembling those of the nose in every respect, except it was more consistent.

Dr. Vander Poel: In reply to the chairman I would simply say that myxomata are essentially embryonic tissue tumors, as myxomatous tissue is only present in the normal adult in a very imperfect and atypical form—as in the vitreous of the eye—and in small amount in the medulla of bone. It is, however, a tissue which readily undergoes transformation, and pure myxomata are not common. They are apt to be combined with fibrillar connective tissue, as fibro-myxoma; or with fat tissue, lipomyxoma; and they frequently become sarcomatous, or take part in the formation of complex tumors. It is therefore to this class of tumor, this degenerated or transformed myxoma, that I believe the chairman refers when he says that he has frequently seen them. What I referred to was a pure gelatinous growth, characterized by stellate fusiform cells, often anastomosing, imbedded in a homogeneous or finely fibrillated, soft, gelatinous basement substance. The case mentioned by Dr. Swain is undoubtedly analogous to the one I have reported. Probably in most cases the diagnosis is made from the macroscopic appearances, and is not confirmed by microscopic examination. I think that originally the growth may be a hyaline myxoma, but subsequently undergoes a change such as I have referred to.

Special Articles.

LETTERS TO MY HOUSE PHYSICIANS.

By WILLIAM OSLER, M. D.,
BALTIMORE.

Letter IV.

Erlangen and Würzburg.

Dear S.: The university is Erlangen—practically there is nothing else in the little Bavarian town, which forcibly illustrates the great truth that *men* make a seat of learning, and, if given proper facilities, will attract students. It is surprising, however, in a place of this size to find so large a hospital; but many patients come from the surrounding country, and there is ample teaching material in medicine and surgery, and even in the special branches.

Strümpell, who has charge of the medical clinic (whose text-book, edited by Shattuck, has made his name well known in America), is one of the most industrious and progressive of the younger generation of German professors. His contributions to neurology have been most important. The medical wards are well arranged, and we were shown a series of instructive cases, several of great rarity. One in particular, of acromegalia, attracted our attention, as it was a most typical instance—a woman, aged twenty-eight, looking over fifty, with large, coarse features, apathetic expression, and enormous hands and feet, which had been, with the face, progressively enlarging for years. The remarkable affection seems rare in Germany, as it is with us. Ever since the publication of Marie's paper I have been on the lookout for cases, and searched in vain the chronic wards at the Philadelphia Hospital. I have known of one case in Toronto for several years, and saw a second in the same town with Dr. Burritt; both of these have recently been described by Dr. I. E. Graham. I see that a special monograph has just been published in Paris on the disease.

A case of rhythmical spasm of the psoas muscles in a middle-aged man, which came on after a sudden paraplegia two years ago, was rather a puzzler for diagnosis. The thighs were lifted with each contraction, and there was a slight spastic condition of the legs. There was evidently organic disease, but the case simulated hysterical rhythmical spasm, an instance of which I remember was shown by Dr. George Ross at the Medico-chirurgical Society of Montreal. Speaking of hysteria, Professor Strümpell sent for photographs of a remarkable case which had recently been under his care, in which the girl had produced extensive lesions of the extremities by cauterization, leaving sloughs resembling somewhat those of symmetrical gangrene. In my last letter I referred to the heart disease induced by the combination of heavy drinking and heavy work, and we found here in one of the wards a most characteristic example: A man, aged about thirty-six, employed in a brewery and accustomed for years to drink from twenty to thirty litres of beer daily, began to suffer with shortness of breath, then œdema of the feet, and finally anasarca of the lower part of the body; in this condition he was admitted to hospital. The heart was much dilated and a loud apex systolic murmur was heard. Under treatment and rest the dropsy was subsiding and the heart's impulse was much more distinct, about two inches outside the nipple line. This, Strümpell said, was a common history in the workers in the large Erlangen breweries. At about the age of forty the breakdown occurred, and usually with heart failure, which proved fatal after two or three attacks. We questioned this patient—a most intelligent fellow—as to the quantity of beer consumed daily by the men, and the figures I mention above represent, he assured us, an average allowance. As might have been expected from the good work which has been done here, there was an excellent collection of cases of diseases of the cord, including one of syringomyelia, and of cases of muscular atrophy, and in the clinical laboratory we were shown many beautiful microscopical sections, particularly of the combined scleroses of the cord. Unfortunately, it was not a clinic day, and we did not hear Professor Strümpell lecture (I had had that pleasure in Leipsic in 1884), but after the hospital visit we spent a couple of delightful hours at his house.

One of the men I was most anxious to meet in Erlangen was Professor Zenker, the describer of trichinosis in man, the discoverer of fat embolism, and the industrious worker at anthracosis and siderosis. He was busy at a Staats-Examen and could not give us much time, but his son and assistant showed us the Pathological Institute, which, though small, is conveniently arranged for teaching. In the post-mortem room we saw a rare termination of mediastinal sarcoma. A man of about forty, with signs of intrathoracic pressure, had died suddenly in the wards. The entire mediastinum was occupied by a large sarcoma, which completely surrounded the great vessels, covered over the heart, and had perforated the superior vena cava, into which masses of the soft tumor projected. Death was no doubt due to extensive pulmonary embolism. As is common in these mediastinal growths, there was extensive pleural effusion on one side, a condition which often complicates the diagnosis.

The new building for the general faculties and the new biological

laboratory (in charge of Professor Selenka) have helped largely in the rapid progress which Erlangen has made as an educational center during the past few years.

Würzburg is the second largest Bavarian university, and its medical school ranks, in number of students, fourth in the empire. The attendance has increased enormously during the past decade, due in part, no doubt, to the attractive character of the new laboratories which have been provided by the government.

The name of Kölliker is not so familiar to English-speaking students of to-day as it was twenty years ago. The new works on histology have displaced the old text-book upon which we, and indeed the generation before us, were brought up, but the man who, forty-five years ago, with Bowman and Goodsir, stimulated the study of minute anatomy, is still vigorous and at work, thoroughly abreast of the times, and a living illustration of the fact that age, after all, is a relative condition. One who has within a few years brought out an elaborate *Entwickelungsgeschichte*, and who, within a month or so, has issued the first part of a new edition of his general histology, twenty-five years after the last edition, can not be called old, though his years may be reaching the Psalmist's limit. I have very pleasant recollections of Professor Kölliker in 1872 and 1873, on the occasion of his visits to dear old Dr. Sharpey at University College. He then was an elderly man, with snow-white hair, and naturally eighteen years have left their traces; but he retains a bodily and a mental vigor which many a younger man might envy, and an interest in all departments of anatomy which it was delightful to see. The new anatomical institute is indeed worthy of the distinguished director, and it was with evident pleasure and pride that he showed us the various divisions devoted to human anatomy, histology, embryology, and comparative anatomy. The museums occupy a large space, as the collections are very extensive; but the laboratory and lecture-room accommodation in this building alone equals the entire teaching space of an average American medical school. Ample provision is made for instruction in the specially practical departments—gynæcological, surgical, and medical—and we found one class-room occupied by a teacher of gynæcology who was lecturing to senior men on pelvic anatomy. The general lecture-room seems exceptionally well arranged for the students, and is regarded by Professor Kölliker, and rightly I think, as a model of the kind. In the histological laboratory it was pleasant to see a son of the late Max Schultze, the founder of the *Archiv für mikroscopische Anatomie*, whose memory will always be held in grateful remembrance by students of microscopy.

The Julius Hospital is an ancient and wealthy foundation dating from the sixteenth century, and is in many parts sadly in need of the renovation which is in progress. The new surgical amphitheatre is the finest which we have seen—very spacious, with tiled floor, glazed walls, iron and oak, open seatings, so that the entire room can be flushed with the hose. The arrangements for patients and assistants seem very perfect in the large suite of rooms opening into the amphitheatre. Hospital authorities in America, particularly those in connection with large medical schools, might consult with advantage the plans of this new building, which apparently combines all the modern antiseptic requirements in a thorough yet plain manner.

In the medical clinic we found Professor Leube with a class of at least three hundred students, who even thronged the arena and the steps of the auditorium. I have already referred to the system of instruction which appears uniform in the German schools. A case of acute yellow atrophy of the liver was shown which had previously been before the class and very unexpectedly had convalesced. Every symptom of the disease had been present, and, in spite of the great improvement, the original diagnosis was maintained, and the professor stated that he had known of one other instance of recovery. The microscopical and chemical examination of the urine was demonstrated by the assistants at very conveniently arranged tables in the arena and without any confusion or disturbance. Upon the next case—hæmorrhage from the stomach—two students were thoroughly and patiently drilled, first, on the general ætiology, and then on the probable special conditions existing in the patient; then followed a summing up, a diagnosis, and the treatment (which in this case consisted in complete abstention from food, with the administration of ergot and opium). Professor Leube is a clear, incisive, and most agreeable teacher, and I envied the students who had the privilege of his instruction.

In the Pathological Institute we were fortunate enough to see a demonstration in the post-mortem room. One of the assistants was instructing a tyro in the technique of an autopsy, while Professor Rindfleisch, with blackboard and chalks and coarse sections, was explaining the anatomy of stone-workers' phthisis. Instead of passing the entire specimen about, small but characteristic portions were distributed on little platters. The whole question of fibroid induration due to dust inhalation was very thoroughly discussed. The remainder of the hour was occupied in the demonstration of the kidneys in a case of acute nephritis in which *macroscopically* there were no changes visible in the cortical part, but with the microscope extensive glomerular disease was found. The post-mortem room is oblong in shape, with a large central area, around which are three tiers of seats for about eighty men. A good view can be obtained from almost any part of the room.

Würzburg has had many notable professors in the past three centuries, but, on leaving the Pathological Institute, I could not but think of the young Berlin prosector who in 1849 found it desirable to accept a chair in this university, and who in the succeeding seven (?) years, by a brilliant series of researches, made the name of Virchow imperishable in our annals and gave the glory to the Würzburg school of a majority of those epoch-making works in the *Gesammelte Abhandlungen*.

Book Notices.

Syllabus of the Obstetrical Lectures in the Medical Department of the University of Pennsylvania. By Richard C. Norris, A. M., M. D., Demonstrator of Obstetrics, University of Pennsylvania. Philadelphia: W. B. Saunders, 1890. Pp. xv–17 to 154. [Price, $2.]

This little book, prepared for the class in obstetrics at the University of Pennsylvania, presents in a concise form an analysis of the lectures which are given at that institution upon that subject. Its range might be widened with profit, and it may be referred to with advantage by students in obstetrics elsewhere, not only by those who are still students in theory, but by those who have been brought into practical contact with the all-important questions of the obstetric art.

Hypnotism: Its History and Present Development. By Fredrik Björnström, M. D., Head Physician of the Stockholm Hospital, etc. Authorized Translation from the Second Swedish Edition. By Baron Nils Posse, M. G., Director of the Boston School of Gymnastics. New York: The Humboldt Publishing Co. Pp. 126. [The Humboldt Library.]

The advantages and dangers of psycho-therapeutics, together with a review of hypnotism from earlier times to the present, and the history of clinical experience with this agent, form the interesting contents of Dr. Björnström's essay. It is a valuable contribution to the literature of the subject, which continues to attract general attention. A little learning is even more dangerous, perhaps, when it is a question of hypnotism than in some other applications of medicine. Hence the importance of all good books that treat of this particular agent.

The Student's Surgery. A Multum in Parvo. By Frederick James Gant, F. R. C. S., Senior Surgeon to the Royal Free Hospital. Philadelphia: Lea Brothers & Co., 1890. Pp. xxxv–817. [Price, $3.75.]

This book is written for the use of English students preparing for their final examination, and seems to be unusually well adapted to the purpose for which it is written. The ar-

rangement is good, it is written very closely, and deserves its title "multum in parvo." The omission of such subjects as the surgery of the eye, ear, teeth, skin, female genital organs, and orthopædic surgery will meet with general approval, for these special lines of surgery have been developed to such a degree that an attempt to outline each would require either the omission of much that is valuable or a great increase in the size of the book, and in either case would detract from its value to students.

BOOKS AND PAMPHLETS RECEIVED.

A Treatise on Massage, Theoretical and Practical; its History, Mode of Application and Effects, Indications and Contra-indications, with Results in over Fifteen Hundred Cases. By Douglas Graham, M. D., Fellow of the Massachusetts Medical Society, etc. Second Edition, revised and enlarged. New York: J. H. Vail & Company, 1890. Pp. x–342.

The Essentials of Medical Chemistry and Urinalysis. By Sam E. Woody, A. M., M. D., Professor of Chemistry and Public Hygiene, and Clinical Lecturer on Diseases of Children, in the Kentucky School of Medicine. Third Edition, revised, enlarged, and illustrated. Philadelphia: P. Blakiston, Son, & Co., 1890. Pp. viii–9 to 157.

A Library of American Literature from the Earliest Settlement to the Present Time. Compiled and edited by Edmund Clarence Stedman and Ellen Mackay Hutchinson. In Eleven Volumes. Vol. XI. New York: Charles L. Webster & Company, 1890. Pp. xxvi–648.

Fifth Annual Report of the State Board of Health of the State of Maine. For the Fiscal Year ending December 31, 1889.

Menstruation and the Removal of Both Ovaries. By George J. Engelmann, A. M., M. D., etc. [Reprinted from the *Transactions of the Southern Surgical and Gynecological Association.*]

Stricture of the Rectum: a Study of Ninety-six Cases. By Charles B. Kelsey, M. D., Professor of Diseases of the Rectum at the New York Post-graduate Medical School and Hospital. Pp. 3 to 41.

The Popularization of Sanitary Science. Annual Address before the Third District Branch of the New York State Medical Association at Syracuse, N. Y., June 19, 1890. By J. G. Orton, M. D. [Reprinted from the *Sanitarian.*]

Transactions of the American Dermatological Association at its Thirteenth Annual Meeting, held at the Boston Medical Library, Boston, Mass., on the 17th, 18th, and 19th of September, 1889.

Report on the Cause of the Recent Outbreak of Typhoid Fever in Waterbury. Made to the Connecticut State Board of Health. By Herbert E. Smith, M. D.

Annual Address on Practice of Medicine. The Mutual Obligations and Responsibilities of the Physician and the People in promoting Medical Science. By W. F. Breakey, M. D., Ann Arbor, Mich. [Reprinted from the *Proceedings of the Michigan State Medical Society.*]

Second Annual Report of the New Amsterdam Eye and Ear Hospital, with Nose and Throat Department. For the Year ending May 13, 1890.

Report of the Trustees of the Newport Hospital. Presented to the Corporation at their Seventeenth Annual Meeting, July 8, 1890.

Appeal for a Ward for Women and Children at the Newport Hospital.

Alter und Neues in der Therapie. Akademische Antrittsrede gehalten in der Aula der Universität Tübingen am 27. Februar, 1890. Von Dr. Hermann Vierordt, a. o. Professor der Medizin. Tübingen: Franz Fues, 1890. Pp. 3 to 26.

Miscellany.

The Medical Department of the Army.—The following circular of information is published for the benefit of medical men who may be desirous of entering the United States Army:

The Medical Department of the Army consists of one Surgeon-General with the rank of Brigadier-General; one Assistant Surgeon-General, one Chief Medical Purveyor, and four Surgeons with the rank of Colonel; two Assistant Medical Purveyors and eight Surgeons with the rank of Lieutenant-Colonel; fifty Surgeons with the rank of Major; and one hundred and twenty-five Assistant Surgeons with the rank of First Lieutenant of Cavalry for the first five years of service, and of Captain of Cavalry subsequently until their promotion by seniority to a majority.

With the rank stated in each case the pay and emoluments of the rank are associated. The salary of each grade is a fixed annual sum payable monthly; but at the end of each period of five years of service the annual sum representing the pay of the grade is increased by ten per cent. until forty per cent. is added. After twenty years of service the forty per cent. additional continues to be drawn, but the further increase of the pay by ten per cent. additions ceases—*i. e.*, an officer, although he may have served twenty-five or thirty or more years, can, under existing laws, have no more than forty per cent. added to his pay proper by way of increase for length of service. The pay of a first lieutenant of cavalry, or of a medical officer during the first five years of his service, is $1,600 per year, or $133.33 per month. At the expiration of his five years of service he becomes, by virtue of that fact, a captain, and his pay is that of a captain of cavalry, $2,000 per year, increased by ten per cent. for his years of service—viz., $2,200 annually, or $183.33 monthly. At the end of his tenth year of service this rate of pay is increased by the service-addition to $2,400 annually, or $200 per month, and after five years more the service-addition makes his pay $2,600 annually, or $216.67 per month. If he continue in the rank of captain, at the end of twenty years of service his monthly pay becomes $233.33; but about this time promotion to a majority is usually obtained, and a major's annual pay of $2,500, with forty per cent. added, makes the monthly pay of the major and surgeon $291.67. Subsequent promotion, investing the individual with the rank of lieutenant-colonel, colonel, and brigadier-general, augments the monthly pay respectively to $333.33, $375.00, and $458.33. Compulsory retirement at the age of sixty-four years increases the rapidity of promotion to the younger men; and when retirement is effected either by age or by the accidents of service prior to reaching the retiring age, the rate of pay subsequently drawn is seventy-five per cent. of the total salary and increases of the rank held by the individual at the time of his retirement. Thus, a major retired for broken health after twenty years' service draws seventy-five per cent. of $291.67 per month; a colonel retired for age, seventy-five per cent. of $375.00. The medical officer has the right of selecting quarters in accordance with his rank, and when stationed in a city where there are no Government quarters commutation money, intended to cover the expense of house rent, is paid to him. The Government provides forage and stable room for the horses of the medical officer, and when traveling under orders the expenses of transportation are paid by the Quartermaster's Department.

Among the privileges granted to medical, as to other officers of the army, is that of leave of absence on full pay. The authorized leave amounts to thirty days annually. This leave is not forfeited if not taken during the year, but is credited to the officer, who may thus accumulate a continuous leave of four months on full pay. If he desire to be absent for a longer period than four months, and the permission is accorded him, he is reduced to half-pay for all time in excess of the four months or maximum of cumulated leaves of absence. Absence from duty on account of sickness does not affect the relations of the officer with the paymaster; he continues to draw full pay.

A commission in the Medical Department of the Army is an instrument which is good for life, premising conduct consistent with its retention on the part of its possessor; but it involves no contract which binds the individual to service for any given number of years. On

contrary, should the medical officer find on experience that civil life has greater attractions for him than that of the army, there is nothing to prevent him from at any time tendering the resignation of his commission.

A young medical officer on appointment is usually assigned to duty for a few months at some large post where there are other officers of his department, to afford him opportunity of becoming acquainted with the requirements of the Army Regulations and the routine duties of military life. After this he goes to some post west of the Mississippi River, where he serves a tour of duty of four years. An assignment in the East follows the leave of absence which is usually taken at this time; and in after years his stations are selected so as to give him a fair share of service at what may be called desirable posts as an offset to the time spent at less desirable stations.

Candidates for appointment to the Medical Corps should apply to the Secretary of War for an invitation to appear before the Army Medical Board of Examiners. The application should he in the handwriting of the applicant, should give the date and place of his birth, and the place and State of which he is a permanent resident; it should be accompanied by certificates based on personal acquaintance from at least two persons of repute as to citizenship, character, and moral habits. Candidates must be between twenty-one and twenty-eight years of age (without any exceptions), and graduates of a regular medical college, evidence of which, the diploma, must he submitted to the Board. The morals, habits, physical and mental qualifications and general aptitude for the service of each candidate will be subjects for careful investigation hy the Board, aud a favorable report will not be made in any case in which there is a reasonable doubt.

The following is the general plan of the examination:

I. The physical examination will be rigid; and each candidate will, in addition, be required to certify "that he labors under no mental or physical infirmity, nor disability of any kind, which can in any way interfere with the most efficient discharge of any duty which may be required."

II. Oral and written examinations on subjects of preliminary education, general literature, and general science. The Board will satisfy itself by examination that each candidate possesses a thorough knowledge of the branches taught in the common schools, especially of English grammar, arithmetic, and the history and geography of the United States. Any candidate found deficient in these branches will not be examined further. The examination on general science will include chemistry and natural philosophy, and that on literature will embrace English literature, Latin, and history, ancient and modern. Candidates claiming proficiency in other branches of knowledge, such as the higher mathematics, ancient and modern languages, etc., will he examined therein, and receive due credit for their special qualifications.

III. Oral and written examination on anatomy, physiology, surgery, practice of medicine, general pathology, obstetrics and diseases of women and children, medical jurisprudence and toxicology, materia medica, therapeutics, pharmacy, and practical sanitation.

IV. Clinical examinations, medical and surgical, at a hospital, and the performance of surgical operations on the cadaver.

Due credit will be given for hospital training, aud practical experience in surgery, practice of medicine, and obstetrics.

The Board is authorized to deviate from this general plan whenever necessary, in such manner as it may deem best to secure the interests of the service.

The Board reports the merits of the candidates in the several branches of the examination, and their relative merit in the whole, according to which the approved candidates receive appointments to existing vacancies, or to vacancies which may occur within two years thereafter. *At the present time there are three vacancies to be filled.*

An applicant failing in one examination may be allowed a second after one year, hut not a third.

No allowance is made for the expenses of persons undergoing examination, hut those who are approved and receive appointments are entitled to transportation in obeying their first order assigniug them to duty.

Copies of examination papers used by the Board in session in New York city in October last are hereto appended as an illustration of the character of the questions submitted to candidates.

Specimens of Examination Papers used by the Army Medical Examining Board, in Session in New York City, October, 1889.

ARITHMETIC.

1. Change ·194 to an equivalent fraction whose denominator is 432.

2. How many inches are there in ·0625 of a yard?

3. What is the percentage of mortality in pneumonia when 13 deaths occur in 64 cases?

4. A harometer indicates 29·36 inches; what is its height in millimetres?

5. 9·17 : 13·83 :: 19·34 : ?

6. What is the cube and cube root of 3·6?

7. By what principle of trigonometry is the distance of certain stars ascertained? Illustrate hy diagram.

8. How do you ascertain the solid contents of a cylinder?

GEOGRAPHY.

1. Name eight rivers of the United States that empty into the Gulf of Mexico.

2. What large lake in the United States is at the greatest altitude? Where is it? And what is its approximate elevation?

3. Give the boundaries of Montana, and briefly mention its general geographical features.

4. Describe the route you would take in going from St. Louis, Mo., to the City of Mexico, and name the States through which you would pass.

5. Mention two or three cities of Europe that are in nearly the same latitude as New York.

6. Name the capital of Saxony, of Bavaria, and of Switzerland.

7. What do you consider to be a small and what a large anuual rainfall?

8. A storm is approaching, passes to the south of the observer in the Eastern United States, and out to sea. Describe the changes of the wind that would occur.

HISTORY AND LITERATURE.

1. Give the names of the principal Roman deities, and the corresponding names used by the Greeks.

2. State what you know in regard to the date and object of the Magna Charta.

3. Who was Galen? And in what century did he live?

4. Give a brief account of Mohammed. In what century did he live?

5. Who was Frederick the Great? Mention some of his victories.

6. Give the particulars of General Arnold's treason.

7. Mention the leading events in the administration of President Madison.

8. Give the names of at least eight of Shakespeare's plays, and the approximate dates of his birth and death.

9. Mention the principal works of Victor Hugo.

10. Name the best-known works of George Eliot. State what you know about this writer.

PHYSICS.

1. What are the differences between the solar day and the siderea day?

2. What portion of the earth's quadrant does the French metre represent?

3. Does the weight of a given mass increase or diminish as you go from the equator to one of the poles? Give the reason.

4. Describe the Torricellian vacuum.

5. Describe the process of ebullition.

6. What is Newton's first law of motion?

7. What is osmosis? What effects have heat and electricity on it?

8. Which color of the solar spectrum is produced by the slowest vibration of ether waves?

CHEMISTRY.

1. Explain briefly the determination of atomic weight by means of specific heat.

2. What other elements belong in the same natural group with sulphur?

3. Describe briefly the chemistry of glass-making.

4. State the physical and chemical properties of aluminium.

5. Mention some of the analytical reactions of the proteids.

6. What are the principal forms in which nitrogen enters into organic compounds?

7. What ptomaines have been isolated? What other substances do they resemble in physiological action and chemical reaction?

8. Mention some tests for morphine.

ANATOMY.

1. Give the origins and insertions of the triceps muscle of the arm. State its actions, and describe its relations to neighboring parts.

2. Give the origin, course, and relations to neighboring parts of the ophthalmic artery, and name its branches and the parts to which they are distributed.

3. Mention the nerves that supply the tongue, and describe the special parts supplied by each, and the kind of nervous supply in each case.

4. Describe the structure, location, attachments, and relations of the ligamentum denticulatum, and state its uses.

5. Describe the structure, course, and relations of the ureter proper.

6. Describe the relations of the trachea in the neck.

PHYSIOLOGY.

1. By what means is the exchange of gases between the blood of the pulmonary capillaries and the air in the air vesicles effected, and what is the nature of the process?

2. State the differences between gastric and pancreatic digestion.

3. Describe the various modes of origin of the lymphatics within the different tissues.

4. Describe the different forms of reflex action, and give an example of each.

5. State the changes that take place in the Graafian follicle, from which the ovum has been discharged.

SURGERY.

1. Describe hospital gangrene, its treatment, constitutionally and locally. What preventive measures check its spread?

2. What are the constitutional manifestations of secondary and tertiary syphilis, and the appropriate treatment?

3. When is phlebotomy demanded?

4. Describe the operation of exposing the inferior dental nerve in its course in the body of the bone.

5. What are the indications for abdominal section or laparotomy?

6. What are the four primary forms of club-foot? Name the contracted muscles in each variety.

7. What pathological condition may follow ligation of veins?

8. Describe the various operations for stone in the bladder.

PRACTICE AND PATHOLOGY.

1. What are the anatomical characters of lymphadenoma?

2. Give the pathology of uræmia.

3. What are the pathological results of chronic alcoholism?

4. What course or courses of treatment would you pursue in cases of acute or chronic dysentery?

5. Give an account of the treatment of acute pneumonia.

6. What are the causes and the usual location of rupture of the heart?

7. Give the clinical history of chronic diffuse nephritis.

8. Give the symptoms of gout, and the differential diagnosis of gout and rheumatism.

9. What is the differential diagnosis of the eruptions of scarlatina, roseola, and measles?

10. Mention the principal animal parasites of man.

OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

1. What are the causes of severe vomiting in pregnancy? How can it be controlled?

2. What is puerperal eclampsia, the means of prevention, and the treatment in early pregnancy and during labor?

3. Describe the utero-placental circulation.

4. Give the signs of pregnancy.

5. What are common causes of abortion? State the preventive measures, and the treatment when it occurs.

6. Give the causes of tedious labor; mention two cases and the appropriate treatment for them.

7. What are the most dangerous diseases of children?

8. What are the earliest symptoms of tetanus nascentium? What are the supposed causes of it?

MATERIA MEDICA AND THERAPEUTICS.

1. Give the source and composition of eucalyptus; name its officinal preparations and dose of each; describe its physiological actions, and state the therapeutical indications for its use.

2. Give the officinal preparations of the mineral acids and doses of each; describe their physiological actions, and mention the therapeutical indications for their use.

3. Give the source and composition of guaiacum; name its officinal preparations and doses of each, and describe its physiological actions and the therapeutical indications for its use.

4. Give the officinal preparations of silver, with doses of each. Describe its physiological actions, and mention the therapeutical indications for its use.

5. Give the source and active principles of ergot; name the officinal preparations, and describe its physiological actions, and state the therapeutical indications for its use.

6. Give the source and composition of erythroxylon; name its officinal preparations, and describe its physiological actions, and state the therapeutical indications for its use.

7. Describe the physiological actions of the bromides.

8. Give the source and composition of gelsemium; name its officinal preparations and dose of each and describe its physiological actions and the indications for its use.

9. Describe the physiological actions of salicin and its derivatives.

HYGIENE.

1. What amount of fresh air per minute should be furnished for each inmate in school-rooms, audience-halls, etc.?

2. What are the effects of exercise on the lungs?

3. What are the possible disadvantages of hot-air furnaces, and how may they be overcome?

4. What is the source and the nature of organic impurities in drinking-water?

5. What can you say of the composition and of the merits of rain-water for drinking purposes as ordinarily stored?

6. What are the advantages and the disadvantages of leavened bread as an article of diet?

7. What is the relative amount of potential energy in the following proximate alimentary substances: Dry albuminate, starch, fat, cane-sugar?

8. By what ordinary means may milk be preserved for a limited time without ice?

9. In purifying an infected apartment by burning sulphur, what quantity of sulphur in proportion to the size of the room would be sufficient?

10. What, in your opinion, is the best method of disposing of excreta? Give your reasons.

Trance following Influenza.—In the *Lancet* for August 16th Mr. Nathan Raw, of the Borough Asylum, Portsmouth, England, quotes Gowers as follows: "Trance or lethargy as it occurs spontaneously is a peculiar sleep-like state from which a patient can not be roused, or can be roused only imperfectly, and which is not due to organic disease of the brain." He then relates the following case: Louisa C., aged thirty-nine, married, was admitted into this asylum on February 24, 1890. She was carried from the cab to the reception room in a helpless state. She could not sit on a chair unless held in position, without which she fell to the ground. Face unusually pale; skin bedewed with cold perspiration. Eyes closed; pupils normal. Limbs relaxed, but when placed in any position remained for some time, until overcome by gravitation. She was apparently unconscious, and could not be roused. Phys-

ically she is a stout, strong woman, with congenital talipes. Heart sounds could hardly be detected even with stethoscope; pulse could only be felt as a minute thread at the wrist, and was 45 to the minute. Respiration slow, shallow, and quiet, and was hardly discernible, 12 per minute. She was placed in a warm bath and vigorously rubbed with towels, with a hope of restoring her to consciousness. Beyond slowly opening her eyes and leisurely looking around, this had no effect, as she at once relapsed into her former unconscious state. She assumed the dorsal decubitus with her arms by her side, and unless carefully examined was apparently lifeless.

March 3d.—For the last seven days she has remained in exactly the same unconscious state, eyes half open, conjunctival reflex present. Pupils act to light. Knee-jerks much exaggerated, no ankle clonus. Apparent cutaneous anæsthesia, as pins stuck into her muscles are not felt. Urine and fæces passed in bed; has refused food absolutely, and has been fed three times a day by the stomach tube with milk, eggs, brandy, etc. Nothing seems to rouse her. Cold water, beyond a momentary reflex effect, is useless; an ice-bag to the spine and a strong current of electricity are of no avail. The nurse on special duty with her this afternoon thought she was dead. When seen a few minutes after she was apparently lifeless, breathing almost imperceptible, and heart sounds could not be detected with stethoscope. A galvanic battery applied over the region of the heart, artificial respiration, and inhalation of nitrite of amyl had the effect of restoring her vital functions a little.

7th.—She suddenly opened her eyes and looked around her, after remaining unconscious for ten days; was persuaded to take a cup of tea; only answered questions in a whisper.

8th.—This morning she was cheerful, talked quite rationally, did not know where she was or when she came; had no memory whatever for the events of the last ten days; took her food well, and sat up in bed.

May 12th.—Talks a good deal about religious matters, but has no delusions; went out to-day on a month's trial.

June 12th.—Was discharged this day recovered.

The following is the history as given by the patient: She has always been hysterical. No history of intemperance or insanity in the family. For several years she has been a diligent student of the Bible, and thoroughly believed everything therein regarding a future state. One month before admission two of her children were taken ill with influenza; after their recovery she herself contracted the disease, and had a most severe attack. The pain in her head was excruciating, and she was quite prostrate in mind and body for two weeks. After spending an anxious day she relapsed into a deep sleep, during which she had a dream, and was awakened by a loud voice, which said, "You are dead." She felt quite helpless, and lay in this state for two days, absolutely refusing all food. When visited by the doctor she informed him she was dead, and wished to be buried. She was at once removed to this asylum as insane. She remembers coming into the gates of the grounds, which she thought was the cemetery. She says that had she been put into a grave she could have offered no resistance.

Remarks.—Some very interesting clinical points arise in this most unusual case. The condition of trance is exceedingly rare in this country, Gowers having seen only four cases. Regarding the diagnosis of the case, I am not yet satisfied as to the true mental condition. Here is a woman whose physical and mental powers are exhausted with the care and anxiety of nursing her sick children; then she is herself prostrated by a severe physical illness with great mental depression. She is not predisposed to insanity either by hereditary transmission or otherwise, but she is undoubtedly hysterical and emotional. Was the woman insane? The voice which she heard was not a true hallucination, as she was unconscious from sleep at the time. Legally, she was insane without a doubt; she was not responsible for her actions, and would have probably died from want of food, the diagnosis thus resting between (1) delusional insanity, (2) hysteria, (3) catalepsy, and (4) trance. She was not suffering from catalepsy, as evidenced by the absence of muscular rigidity; nor were the symptoms purely hysterical, as shown by the utter impossibility to restore her to consciousness. Then regarding insanity pure and simple, this is negatived by the fact that she has no memory whatever for what occurred during those ten days, and the sudden and complete recovery from all the symptoms. I am inclined to think that this was a case in which, from severe nervous exhaustion and with a predisposition to emotion, the patient's mind was temporarily unhinged, and that the trance condition was due to an inhibition or arrest of action of the nerve cells, probably from previous exhaustion.

Sea Voyages.—"A correspondent writes: 'I am glad to see in the *Lancet* an article saying so much in favor of sea voyages, but I think you have omitted one very important point—viz., the very great advantages of a sailing ship over a steamship, such as the greater cleanliness, freedom from smoke, and especially the freedom from that most unpleasant oily smell of the engines, also the greater size of the cabins. I speak from experience of a voyage to Australia and back in sailing ships, from which I derived much benefit. I was lately in a steamship and was greatly surprised at the difference; go where I would on the ship, I could never escape from that oily smell of the engines. The food on the sailing ship was very good indeed.' Exigencies of space forbade a comparison of the merits of sailing vessels and steamships in the article to which our correspondent refers. The point is, however, well worthy of attention, and the advantages of a sailing vessel enumerated above are real and important. A sailing vessel is usually cleaner, quieter, and roomier (in proportion to the number of passengers) than a steamer, and on a long sea voyage the importance of cleanliness, quiet, and space can hardly be overestimated. If no other considerations had weight, it would not be difficult to lay down the rule that for invalids a sailing vessel should always be preferred to a steamer. But the question is more complicated than our correspondent's letter would seem to indicate. A sailing vessel is open to the objections that the voyage is sometimes very prolonged and monotonous, that the detention in the hot and moisture-laden atmosphere of the Belt of Calms may extend to a week or a fortnight, and is a very trying time, and that few or no opportunities are afforded for touching at ports to obtain fresh vegetables, fruit, etc. Some animals, such as pigs and ducks, thrive well at sea, and their flesh remains agreeable and nutritious; but sheep and bullocks, not to mention chickens, turkeys, etc., nearly always show more or less deterioration in the quality of their meat after a few weeks at sea. Steamships with their ice chambers can surmount this disadvantage, but it is generally more or less felt on sailing ships, above all if the voyage is very prolonged. There is another point that must be kept in view in considering this question—viz., that steamships are more and more driving sailing ships out of the trade, and that the choice among the former is very much wider than among the latter. We mention these facts in order that the *pros* and *cons* of the case may be kept before our readers, but we by no means wish to imply that steamships should generally, and as a matter of routine, have the preference over sailing vessels. . . . Much will turn upon the patient's malady, and upon his general constitutional state and usual mode of life. For serious cases (when such can be prudently sent to sea at all) a sailing vessel, always provided that reasonable comfort can be assured, will generally be preferable. Life on a steamship is too much like life in a hotel to suit such cases. Again, if the patient be specially desirous of perfect rest and quiet, a sailing vessel will best meet the case. On the other hand, if the case be one mainly requiring change and travel, if the patient likes company and must have variety and amusement, and if he can not be content without a very liberal and constantly varied dietary, then a first-class steamship will probably please him best. Some patients, again, want 'to see the world,' and take great delight in the various calls made at different ports. Such persons must remember that sailing vessels hardly call anywhere, and very commonly make the long voyage to the Antipodes in a single run. Probably a well-appointed yacht affords the best type of what is most desirable for travelers by sea; and, while such is only at the disposal of a very limited number of patients, it is possible that 'invalid ships,' which are now becoming a recognized institution, may be gradually approximated in some degree to this type."—*Lancet.*

Sugar in the Blood.—"The condition known as mellitæmia, or the presence of sugar in the blood, has long been recognized. Pavy, Ewald, Seegen, and Otto have demonstrated beyond doubt that sugar is a normal constituent of the blood, although it is present only in very

small proportions: the quantity is not altered when the blood is analyzed after death. The proportion of sugar in the blood is considerably raised in cases of diabetes. In 1885 Freund examined the blood of seventy patients suffering from carcinoma, and found it to contain a large quantity of sugar, but he was unable to detect it in cases of sarcoma. Freund's experiments have not been fully verified by other observers. In the *Centralblatt für die medicinischen Wissenschaften*, 1890, No. 25, Trinkler gives an interesting account of a series of observations he has made as regards the amount of sugar contained in the blood in various diseases. He examined the blood of one hundred and nine patients, and the investigation fell into two classes: 1. Quantitative estimation of sugar and reducing substances in the blood during life, the quantity of blood required being obtained during the performance of operations. 2. In which the greater number of analyses took place after death. The diseases from which the patients were suffering were carcinoma, typhoid fever, pneumonia, morbus cordis, dysentery, peritonitis, nephritis, uræmia, etc. Sugar was found to be present in all the cases. In carcinoma the amount was very large; next came typhoid fever and pneumonia, while nephritis and uræmia exhibited the least. In the case of carcinoma the following conclusions could be drawn: 1. The blood of patients suffering from carcinoma always contained a considerable percentage of reducing substances, of which the chief was grape sugar. 2. The maximum percentage of sugar in the blood of living patients was less than the maximum obtained after death. 3. Carcinoma affecting the internal organs produced a greater quantity of sugar than when attacking superficial structures (skin, mucous membranes). 4. The degree of cachexia stood in no direct proportion to the percentage of sugar in the blood. The quantity of sugar in acute pneumonia, typhoid fever, and dysentery was about the same, and very little above the normal; while in nephritis, and especially in uræmic conditions, the quantity was below the normal."—*Lancet.*

Mortality in Cities in the United States.—The following table represents the mortality in the cities named, as reported to Dr. John B. Hamilton, Surgeon-General of the Marine-Hospital Service, and published in the Abstract of Sanitary Reports for August 29th:

CITIES.	Week ending—	Estimated population.	Total deaths from all causes.	DEATHS FROM—										
				Cholera.	Yellow fever.	Small-pox.	Variboid.	Varicella.	Typhus fever.	Enteric fever.	Scarlet fever.	Diphtheria.	Measles.	Whooping-cough.
New York, N. Y.	Aug. 23.	1,638,498	751	..	..	..	..	..	..	12	4	14	12	16

Sickness as a Teacher.—"All the circumstances of life," says the *Lancet*, "are in some sort educative. Health and happiness have their lesson of active duty to teach us if we will receive it, and so, likewise, have pain, disease, and misfortune, as lately stated by Mr. Spurgeon, a purpose of correction, a chastening and a mellowing influence within them. With some natures and moods, perhaps, it is otherwise; the sharpness of the stroke touches no mental spring but that of self-concern, but here, again, it is the wise who learns. For him these evils, for such they still remain, are also the seeds of sympathy with others in like trouble. If he be through any fault of his own accountable for them, they are in true science as in Scripture the natural recompense of evil, a protest on behalf of needful self-control which he will do well to observe. There is more, therefore, than an apparent tendency to asceticism in this doctrine of disciplinary suffering. Of course, it does not follow that the prosperous and the healthy must at some time undergo this training by reverses. The same lessons of patience, fellow-feeling, and self-restraint can be learned in other ways, and it is quite certain that the daily round and task abound in opportunities for such wholesome instruction. We are alike justified, therefore, in admitting for this purpose the frequent utility of pain, and in seeking, to the best of our ability, to limit and to destroy by suitable remedies the influence of this otherwise harsh and hurtful instructor. Health of mind and body and well-being of estate are alone consistent with perfect life as ordered by Nature's plan and the Divine will, and every purpose of training is compatible with their full possession and their proper use."

To Contributors and Correspondents.—*The attention of all who purpose favoring us with communications is respectfully called to the following:*

Authors of articles intended for publication under the head of "original contributions" are respectfully informed that, in accepting such articles, we always do so with the understanding that the following conditions are to be observed: (1) when a manuscript is sent to this journal, a similar manuscript or any abstract thereof must not be or have been sent to any other periodical, unless we are specially notified of the fact at the time the article is sent to us; (2) accepted articles are subject to the customary rules of editorial revision, and will be published as promptly as our other engagements will admit of—we can not engage to publish an article in any specified issue; (3) any conditions which an author wishes complied with must be distinctly stated in a communication accompanying the manuscript, and no new conditions can be considered after the manuscript has been put into the type-setters' hands. We are often constrained to decline articles which, although they may be creditable to their authors, are not suitable for publication in this journal, either because they are too long, or are loaded with tabular matter or prolix histories of cases, or deal with subjects of little interest to the medical profession at large. We can not enter into any correspondence concerning our reasons for declining an article.

All letters, whether intended for publication or not, must contain the writer's name and address, not necessarily for publication. No attention will be paid to anonymous communications. Hereafter, correspondents asking for information that we are capable of giving, and that can properly be given in this journal, will be answered by number, a private communication being previously sent to each correspondent informing him under what number the answer to his note is to be looked for. All communications not intended for publication under the author's name are treated as strictly confidential. We can not give advice to laymen as to particular cases or recommend individual practitioners.

Secretaries of medical societies will confer a favor by keeping us informed of the dates of their societies' regular meetings. Brief notifications of matters that are expected to come up at particular meetings will be inserted when they are received in time.

Newspapers and other publications containing matter which the person sending them desires to bring to our notice should be marked. Members of the profession who send us information of matters of interest to our readers will be considered as doing them and us a favor, and, if the space at our command admits of it, we shall take pleasure in inserting the substance of such communications.

All communications intended for the editor should be addressed to him in care of the publishers.

All communications relating to the business of the journal should be addressed to the publishers.

Lectures and Addresses.

THE BLOOD AND BLOOD-VESSELS IN HEALTH AND DISEASE.

AN ADDRESS DELIVERED BEFORE THE OTTAWA MEDICAL SOCIETY, *May, 1890.*

BY WESLEY MILLS, M. A., M. D.,
PROFESSOR OF PHYSIOLOGY IN MCGILL UNIVERSITY, MONTREAL.

GENTLEMEN: Our knowledge of any subject may perhaps be regarded as a perception of relations. As these, however, are innumerable, the great question becomes, What relations are of the most importance? From what point of view shall we look at a subject? Necessarily this must vary with the progress of all knowledge and with that of any department under consideration.

When the period of derision and skepticism that followed at once the announcement of the discovery of the circulation of the blood by Harvey had passed away, and a body of practitioners less prejudiced than the great man's own contemporaries considered the subject, a reaction took place. Undue attention was given the blood in all discussion on the ætiology of disease.

In comparatively recent times the investigations of blood-pressure and kindred problems by Ludwig and his school diverted attention unduly to that subject, and the influence of this is evident in almost every text-book on physiology at present extant. Believing myself that physiology has been confined within extremely narrow limits, that it must in consequence suffer from the intellectual myopia of its cultivators, I have within the past year endeavored to present to the student of this science a work * on a new plan, and it is my purpose this evening to ask your consideration to its advantages, which I shall endeavor to present as applied to the subject of this address, and leave you to judge for yourselves whether this method of viewing the subject gives a wider and truer view of physiological truths than the older plan or not.

We all recognize the fact that any individual can be but indifferently understood apart from his antecedents; hence the importance we attach to biographical sketches of those persons that interest us. It is really an acknowledgment of the influence of the environment on the organism, both during its own life-time and that of its ancestors.

Why, then, is not the consideration of every function of the body preceded by an account of the development of the structures involved as well as by ordinary anatomical or histological details?

No advanced morphologist hopes to clear up the relations of any animal group without taking its embryology into consideration. Up to the present this method has been almost wholly ignored by physiologists. Allow me to suggest in this connection a few considerations which seem to put the student in the possession of a clew to otherwise very obscure relations.

All are agreed that whatever the later history of the blood-cells, they arise in the embryonic mesoblast at the same time as the heart and blood-vessels themselves. To consider, therefore, the heart, blood-vessels, and blood wholly separately, or without a perception of their unity, is a mistake that has practical as well as theoretical consequences. When we bear this relation in mind, it is possible to understand that there may be cases in which the whole vascular system, including the contained blood, may be imperfectly developed, and with all the consequences of recurrent anæmia. There can be no doubt that any crop of blood-cells must bear relations to the preceding one, and if the original ancestors are defective, their descendants are likely to be similarly weak, apart from any unfavorable circumstances in the environment.

Until recently the functions of the white corpuscles, if considered at all in works on physiology, were dismissed in a very few lines. When we remember that the leucocytes of the blood correspond to the original indifferentiated embryonic cells, which alone have made up the entire embryo and are preserved as floating organisms with a latent capacity for further development, much light is thrown upon both physiological and pathological processes. Whatever the view that finally prevails as to their relations to invading micro-organisms, there can be no doubt that as scavengers, porters, or phagocytes their function is of great importance; yet, apart from a consideration of their origin, this can be but indifferently understood. It is well known that the undifferentiated cells of the embryo are more or less amœboid organisms; hence it is perfectly natural that their descendants should, under suitable circumstances, exhibit those qualities which recent investigators are showing more and more that they possess. The great part they play in inflammation is also more readily comprehended. In this condition there is a profound alteration in the environment, as will be shown later.

At present our positive and clear knowledge of the red cells of the blood is confined to their oxygen-carrying function; but I feel satisfied that this does not include all their work and that we must look for a very considerable enlargement of our knowledge of the range of their duties. Indeed, it would seem that we are in great danger now of going to an extreme the opposite of that of our ancestors and attributing too little to the blood, especially its cells. It is not to be forgotten that the blood as a whole is to be regarded as a tissue, and there is no more reason why this tissue should be devoid of functions than any other.

Most of our works on physiology so present the subject to the student that he has no clear ideas as to *how* the blood does minister to the tissues, though every one is ready to say at once that the function of the blood is "to nourish the tissues." In truth, some very remarkable doctrines have been taught in regard to the relations of the blood and blood-vessels. As a rule, students have the most misty notions of the relations and importance of the lymph. They know that it flows in "the lymphatics," that it gets into the blood-stream finally, that it is in some way derived from the blood, etc. But there is no clear perception of

* *A Text-book of Animal Physiology.* D. Appleton & Co., New York, October, 1890.

these relations, and it is impossible that there should be with the teachings that are prevalent.

The books represent the lymph as passing through the capillaries; but, if any explanation of this process is given at all, it is represented as a filtration—very much of the character of that "filtration" of urine through the capillaries of the Malpighian capsules which has been so commonly taught up to the present as dependent almost solely on blood pressure.

This doctrine has seemed to me so utterly at variance with all sound biological laws that for three or four years I have been accustomed to teach in my lectures, and have recently published in my text-book, a theory which I must present to you with brevity, but which I am sure you will see places the physiologist, the pathologist, and the practitioner of medicine on an eminence from which they can view the events of the body in an entirely new light. It is simply this: *The capillaries of the body are glands.* They are glands not only in the glomeruli of the kidney, but everywhere else. So far as I know, I have been the first to teach this doctrine; I must therefore give you, at least in a general way, the reasons for my conviction.

In the first place, I should be prejudiced against any biological doctrine that would represent a living structure as acting as a mere filter, or as teaching that osmosis played any considerable part or, in the strict sense, any part at all when living structures, "membranes" or other, were concerned. There seem to be no facts that can not be better explained without such an assumption; and, even if this were not the case, it is better not to construct a theory at all, but simply confess ignorance and wait, than one which like this is radically opposed to all sound conception of living structure.

To believe that the lymph which bathes each tissue is identical in composition is to overlook the relations of the blood and blood-vessels to the tissues among which they have been developed. But the lesson Nature everywhere teaches is that things do work in relation to each other.

What a crude conception of life processes to suppose that the capillaries pour out a fluid around the cells of the tissues whose composition is not specially related to the needs or peculiarities of each one!

But the facts we do know are opposed to such a view.

All exudations or transudations are not alike in chemical composition; nor are passive exudations identical with inflammatory ones. Can osmosis explain this? Can it explain why an inflammatory exudation does not correspond with the normal tissue-lymph? Can it give a reason why there are coagulable proteids in lymph or any of the fluids that are derived from the blood at all? While the facts can not be explained by osmosis, they are all simple enough when we view the capillaries as glands—*i. e.*, as passing from the blood to the tissues, and the reverse, an elaborated fluid which varies with the condition of the cells composing the capillary and the tissue-cells that surround it. That the condition of the blood can modify the capillaries, the latter the blood and the tissues both, is to my mind clear enough. To put it otherwise: The tissue-cells around a capillary, the capillary cells themselves, and the blood are always in a sort of balanced relation. They understand each other, so to speak, and act in harmony. One can not be disturbed without affecting the other.

When a great derangement occurs, what we call inflammation arises, and, sooner or later, all the parts of this inseparable trio become involved. In inflammation we have changes in the blood-cells, changes in the vessel-walls, and changes in the surrounding tissue-cells. The embryological history should have led us to expect all this.

When this relation of the capillaries as secreting mechanisms is understood, many of the difficulties that surround "digestion" and "absorption" will be removed. Time will not allow of my developing this part of the subject at length now. In my opinion, there is no sharp line to be drawn between digestion and absorption. They are parts of one great series of processes. Not only so, but the term absorption is misleading, as it suggests purely physical processes, which latter must always be dealt with very cautiously by physiologists.

If, for example, we regard the capillaries of the alimentary tract as glands, it will no longer be impossible to understand that the peptones of digestion are not represented by peptones in the blood, the great stumbling-block of physiologists for long enough.

Intracellular digestion is not confined to invertebrates. The cells of the digestive tract, those of the capillaries included, have not wholly forgotten the amœboid habits of their embryonic ancestors. They are specialized, it is true, but not wholly altered. To suppose that digestion or the physical and chemical alteration of food ends within the cavity of the alimentary tract is to overlook a large part of the truth. Food is changed there by virtue of the digestive secretions, but all is not thus done. In fact, what is commonly termed digestion is only the beginning of a long series of processes which go on in the cells of the structures of the tract, the capillaries included, in the blood itself to some extent, and which continue under the name of metabolism in the tissues themselves. But it is the separation and isolation in the mental conception of the student of what must be linked in one long chain that is to be especially dreaded in the modern teaching of physiology.

A student may throw a great part of the facts of his physiology overboard after his examination, but the influence of his teaching must last for good or evil in all his thinkings as a practitioner. That a sounder view of the processes of digestion, etc., would greatly modify practice, and especially would explain present failures and successes, is clear to myself. Any attempt, however, to make this evident to others must be left for another occasion.

It may, without exaggeration, be said that the application of the principles of evolution to morphology has revolutionized the teaching of that subject. But, strangely enough, its great doctrines have thus far made very little impression on physiology, especially the teaching of the subject; and my own text-book is the first and only one in which an attempt has been made to light up the student's path with this theory, and you will be glad to hear that this effort has been rewarded by increased interest in physiology

on the part of my own classes during the four years of trial of the new methods of presenting the subject.

But if this is good for students that are undergraduates, may it not also prove helpful to practitioners to regard disease in the light of evolution?

Physicians have given but little attention to the subject. To this statement, however, there are at least two notable exceptions: the late brilliant Milner Fothergill, and that profound thinker, of whom we are all so proud the world over, Hughlings Jackson.

Turning to the vascular system in the wider sense (the blood and blood-vessels), by the help of evolution and embryology not only are many anomalies of vessels understood, but of the blood itself.

Does not a case of extreme multiplication of leucocytes in the blood indicate a condition at once embryonic and ancestral? In other words, is this not an example of physiological or pathological reversion? In the early embryo, leucocytes are very abundant everywhere, and in invertebrates, almost without exception, they or their equivalents are alone found, while in the lower vertebrates they are both numerous and of very much more pronounced amœboid character than in the higher. Is not this tendency, then, on the part of the higher mammals and man, under certain circumstances, to an excess of leucocytes in the blood better understood than without the explanation of evolution? Why this particular form of derangement, and not some other, if higher forms are not related by descent to the lower?

Again, in the various forms of anæmia we find red cells that are nucleated, cells smaller or larger than normal, distorted cells, corpuscles resembling the genetic marrow-cells, etc.

All these forms occur in the embryo, apparently normally; some of them are certainly transition forms. They also bear a resemblance to the red cells of lower vertebrates. Are these not clear cases of reversion to an earlier condition, both embryonic and ancestral? Even that form of anæmia in which the cells are fairly normal, excepting a deficiency in hæmoglobin, points to the lower vertebrate and invertebrate blood, which is, relatively to the higher groups of animals, poor in hæmoglobin.

Inflammation itself, both as regards the vascular system and the tissues, becomes clearer from the standpoint of evolution. The increased amœboid activity of the leucocytes, the alterations in the latter and the vessel walls permitting of the ready "wandering" of the colorless blood-cells, point to a condition of things common in lower vertebrates. Inflammation is clearly a reversion.

Reference might be made to the resemblance between the condition of things in the young mammal—in which, after birth, the usual changes that fit it to its altered environment do not take place—and the permanent state of the heart and vessels in lower vertebrates, as reptiles. However, the illustrations employed may suffice to show that evolution does concern the physiologist, the pathologist, and the physician; and, did time permit, I think I could demonstrate that such views may be made to have a bearing on the treatment of disease by the most enlightened methods. The subject has been dealt with further in its relations to medicine elsewhere.*

I shall not pursue this line of thought further at present, but leave you to judge for yourselves whether the time has come when students and practitioners should be provided with text-books of physiology in which attention is paid to general biology, comparative embryology, and evolution, with a view of giving a wider and truer grasp of the functions of those organisms with which the great art of medicine is concerned.

Original Communications.

A CASE OF PSEUDO-HYPERTROPHIC PARALYSIS COMPLICATED BY A FRACTURE OF THE LAMINA OF THE FIFTH CERVICAL VERTEBRA; *A Contribution to the Physiology of the Spinal Cord.*†

By N. E. BRILL, A. M., M. D.

It is so seldom that an opportunity arises in the human species to make an *intra-vitam* experiment on the spinal cord, that the following case is of unusual interest:

James G. K., twenty six years of age at the present time. No history of neuropathies in his family. At the age of eight months made successful attempts to walk with the supporting aid sometimes of a chair and sometimes of the wall. At this period, while being weighed in the following manner—he was placed in a blanket, his head and legs dangling over the sides, the rest of the blanket being tied into a loop which was held by the hook of an old-fashioned scales—his head was wrenched by the violent oscillations of the spring of the scales. Although the age at which he made his attempts at walking was a remarkably early one, there can be no doubt as to the fact that these attempts were then frequently made by him. They were made spontaneously and without assistance on the part of his parents. After the weighing episode, however, he could make no further attempts, his failure to walk extending then until the age of twenty-two months. Nothing unusual was noticed by his parents during the months following the weighing, excepting his desisting in making further trials at walking. These he resumed at the last-mentioned period, and progressed until he walked without any support. His walk was, however, peculiar, being attended by swaying motions which gave him the name of a "toddler." From this time to his tenth year nothing of note occurred. The only fact remarked was his liability to stumble, to stub his toe in walking, and to fall whenever he encountered any obstacle like a play-toy which might happen to lie on the floor in his path. He could walk and run, the latter not as swiftly as his companions, but he could keep up his pace for longer distances than they. He indulged in all the sports of childhood, and in the acrobatic feats usually performed by boys living in the country. He could turn handsprings with great agility. At his tenth year, while indulging in the latter exercise on a load of hay, the hay not being packed or compressed, his hands sunk into it, and, in throwing his legs over in

* Physiological and Pathological Reversion. *Canada Med. and Surg. Journal*, April, 1888.

† Read before the American Neurological Association at its sixteenth annual meeting.

the accomplishment of the feat, his head was caught or wedged in the hay. He felt a sudden pain and shock in the neck, and remarked to his playmates that he thought he had broken his neck. He immediately proceeded to the house, and, although at that time he detected nothing unusual, he dates all the subsequent trouble to that event. Besides pain and stiffness in the back of the neck, he noticed a diminished amount of lateral motion and difficulty in rotating the head, the movement being more restricted in turning the head to the left than to the right.

Shortly after the accident—he can not say definitely how long thereafter—he noticed that his "ankle would move rapidly up and down" whenever he put the ball of his right foot in a certain position (ankle clonus). The same symptom appeared in the left foot about two years afterward. Until his fourteenth year, four years after the accident, his attention was directed to no other abnormal phenomenon. But at this period of his life he found that while walking his *right* "knee would give way," that is, it would suddenly bend beneath his weight, doubling up in flexion, and, unless he exercised great care, he would fall to the ground. He soon found his right leg would become tired and his gait became different. This weakness, as he describes it, in the right leg increased, the knee would bend more and more frequently, and the same phenomenon began to develop in the left knee. It was exactly two years after the first sign in the right knee showed itself that the left knee became affected. The same changes developed in this extremity as in the right. At the same time that changes were beginning to manifest themselves in the left lower extremity he detected that his right hand and forearm would quickly become tired while milking the cows. This was his usual occupation at home, and his inability to continue it on account of rapidly developing weakness in his arm alarmed him. The weakness of the right upper extremity kept step in development with that of the left lower, and when they had reached a high degree the same appeared in the left upper extremity. It was about two years after the first sign of weakness showed itself in the right upper that he detected the presence of it in the left. The latter underwent the same loss, and he found himself unable to raise his arms to a level with his shoulders. It was a difficult matter for him to button his collar to his shirt in the back; he was compelled to give his arm a swing to get his hand to his head, and it was in this way that he succeeded in accomplishing that part of his toilet. He then sought medical advice and treatment. The latter embraced almost everything between the extremes of "laying on of hands" and electricity. As to the diagnoses given, the less said the better. Dr. Spencer, of Watertown, N. Y., was perhaps the only individual who appreciated a serious organic lesion of the cord. It was he who brought him to New York for the purpose of obtaining an authoritative opinion, and for treatment. This was the history given by the patient, and, being a very intelligent young man, observant and reflective, the points elicited by subsequent examination were very satisfactory; many of his spontaneous descriptions corresponded to the course and distributions of the nerves and their functions, although the patient has no knowledge of anatomy or physiology. He mentioned, in addition to the previous signs, an inability at times to grasp objects on account of a sudden and spasmodic retraction of the arm, forearm, and fingers which forcibly drew them away from the desired object, these members of the upper extremity undergoing twists and turns, sometimes being drawn to a position behind his back. During my examination I had the good fortune to observe one of these athetotic movements.

Status præsens.—Patient is about five feet six inches and a half high. Walks with the aid of a cane, steps slowly and deliberately, each foot after leaving the ground being forcibly retracted, giving a good example of the spastic gait. In ascending stairs he supports himself with his right hand on the wall or balustrade, puts his left foot forward, his left hand on his left thigh directly above the knee, and lifts himself in this way up to each successive step. In descending he uses the wall or balustrade support, puts down his left foot upon the step and his right foot is jerked after him, step by step. This evidently shows a greater loss of muscular power in the right lower extremity than in the left.

His head assumes a peculiar position, being lowered, as it were, to an abnormal degree between the shoulders and bent considerably forward, his chin approaching his chest. A transverse furrow in the muscular structures in the back of the neck is present, and, on putting the finger therein and pressing upon the spinous processes, the fifth cervical spinous process can not be felt. It seems to have been either destroyed, perhaps by absorption, or undeveloped, by reason of a defective blood supply occasioned by the accident. When asked to rotate his head, he does so slowly and methodically, feeling each successive step in the arc described; normal rotation is interfered with to the extent that, on turning the head to the left, it describes an arc of about 30° only, to the right one of about 50°. He carries his head stiffly, avoiding all rotatory motion. He likewise bends his head forward and backward to a limited extent, but flexion and extension are more readily performed than rotation.

In speaking, he moves his lips, keeping his jaws quiet, so that his face appears to be immobile. This is done to avoid the fatigue which the muscles of the neck undergo in conjunction with the facial muscles in this act. He thus requires all the muscular power he has in supporting his head, avoiding all extra and unnecessary efforts.

On stripping him, a remarkable atrophy of certain muscular groups is observed, wasting being especially observed in the clavicular, scapular, humeral, and femoral groups.

The clavicles stand out very prominently, owing to the atrophy of the pectoralis major, the deltoid, and subclavius below; the acromial end, the head of the humerus, and the acromion of the scapula likewise appearing beneath the skin as distinctly as in a dissection.

The scapulæ show the "angel-wing" appearance, owing to the wasting of their muscular groups.

In the arm the wasting is extreme, the forearm and hand appearing overdeveloped. When questioned about the latter muscles, he stated that in them the first signs of weakness and wasting appeared after the legs had been involved, and that he noticed these signs first in the thenar and hypothenar eminences, but that these groups subsequently, together with the muscles of the forearm, increased in size, so that at the present time they are actually overgrown, although they present the same weakness. (See cuts.)

On looking at the lower extremities we are struck by the overdevelopment of the legs, the circumference of each calf being equal to that of its respective thigh in its middle third. The thighs, however, present the same atrophy which was noticed in the upper extremity, all the muscles being involved. Owing to this atrophy, the patient stands with his legs apart, and presents a marked convexity in the popliteal region, which, instead of showing a depression, bulges out to complete with the gastrocnemii a continuous convex curvature. The atrophy is greater on the right than on the left side. (Fig. 2.)

The gluteal muscles appear to be unaffected, the buttocks standing out prominently. They, however, are the seat of the same changes as were noticed in the calves. Both erectores spinæ are also involved in this hypertrophic change. As a result, the back presents a marked concavity in the lumbo-sacral

region, the muscular masses of the erector spinæ rising on either side, causing a deep longitudinal, lineal furrow, as is well shown in Fig. 2.
